If the test is positive, tuberculin treatment should be begun at once. Tuberculin, moreover, if properly used, affords the only absolute means of diagnosis in incipient cases, and in such cases, in the hands of an expert, a cure can be usually guaranteed if the surroundings of the patient are reasonably favorable and if the patient and his friends will heartily co-operate with the physician in carrying out the details of the treatment.

The success of the Bang treatment in eradicating tuberculosis from a herd of cattle has already been adverted to in this paper. It is perhaps needless to remind you that the subcutaneous tuberculin test is absolute in cattle. It is not so generally known, however, that many young cattle recover spontaneously from tuberculosis. Efforts, however, to immunize them by attenuated cultures of human or bovine tubercle bacilli have not, so far, been successful, at least to any marked degree. Further experiments, however, carried out upon similar lines, are urgently needed. Prof. Theobald Smith informed the writer that he intended to institute such experiments in the Rockefeller experimental station at Princeton. He recommends that in the treatment of tuberculosis with tuberculin, reliance be not entirely placed upon O. T. (Koch's old tuberculin). This point is mentioned here to show how extremely careful one should be in using any form of tuberculin. Some operators prefer the O. T., others the T. R., and still others the B. E. A consideration of the merits of these and other preparations of tuberculin would take up too much of our space at this time. In point of fact, the choice of the best form of tuberculin rests largely with the operator, and the results depend chiefly upon his judgment and skill. A plowboy cannot, as a rule, successfully run a steam engine, nor a woodchopper play a church organ. It takes much technical skill as well as extensive reading and trained judgment to use tuberculin properly. Eminent practitioners and good clinicians have turned away from tuberculin treatment with sorrow and disappointment. They had set out to build their tower without counting the cost. It takes a man with the proper temperament, as well as the necessary skill and experience, to use tuberculin successfully.

Nor should any one expect a half-fed worker in an unwholesome trade, who is an excessive user of tobacco and spirits, to prosper under tuberculin treatment. Nothing must be left undone to place the patient in the most favorable position, mentally, morally, and physically during his whole treatment, if a favorable result is to be expected.

Klebs says tuberculin (properly used, of course) will do no one harm who is well fed. Lowenstein saw 20,000 single injections without a bad result or a single death. And Beck states that in Koch's Institute for Infectious Diseases at Berlin 2,508 cases received tuberculin treatment, and no inconvenience or bad results were observed.

Having then this practical diagnostic agent and this invaluable method of treatment, why do we delay, linger, and wait before putting it into use? Pottenger has used it twenty-five years, and told the writer only last week that he has not discontinued its use. Von Ruck, Longstreet Taylor, Solis-Cohen, and our own Doctors Gray, Twinch, Scheppach, and Banks have not lost their interest or enthusiasm in this method of treatment as their experience and knowledge have increased. Personally, I am free to say that I look upon Dr. Ellis Bonime, who has perfected and amplified the treatment of tuberculosis by tuberculin and by vaccines, as a genius, and a man whose name will be revered in the annals of medicine when his detractors have been forgotten.

The first three questions in the published synopsis of my paper have been measurably answered in the contex:

Tuberculin is unquestionably the best test for the early diagnosis of tuberculosis.

In the writer's opinion, it should always be used in cases of tuberculosis which are not so far advanced that tuberculin may be actually harmful, because the body cells are so completely exhausted that they cannot respond to the stimulus of the injected tuberculin and throw out the antibodies which finally overcome the infection from the tubercle bacilli already present in the body.

In a lecture before the Orange Mountain Medical Society, May 18, 1917, Prof. Richard Weil advised the use of tuberculin, saying that it immunizes the cells to the toxins of the tubercle bacillus, and although it does not and cannot produce absolute immunity against the disease, it places the patient in the most advantageous position to withstand the infection.

If, then, for the sake of argument, we admit that tuberculin, properly administered, is an invaluable aid in the war against tuberculosis, is there any prospect that it can be so generally employed as to reach even a small percentage of those infected with the disease?

There seems to be no efficient method of accomplishing this except by the general establishment of tuberculin dispensaries all over the country, in the proportion of one dispensary to every 30,000 inhabitants. Most encouraging reports are received from England and Germany regarding the good results of dispensaries that have been established in those countries. Simon, in his well-known work on "Infection and Immunity" (page 213), in speaking of the general treatment of tuberculosis by tuberculin, states that: "Treatment with old, followed by new tuberculin, was mostly used in advanced cases, and seems to have furnished the best results, as gaged by the disappearance of the bacilli in thirty-eight of sixty-nine cases; *i.e.*, in 55.07 per cent. Considering the advanced character of the lesions in these individuals, this is indeed quite remarkable. If we contrast these findings with the results of a purely expectant (*sc.* hygienic-dietetic) plan of treatment, where only 20 per cent. of the cases show loss of bacilli, no further argument in favor of the tuberculin treatment is required."

He goes on to state: "Of late, systematic efforts have been made to improve the hygienic condition of the tubercular poor and to give these also the benefit of the tuberculin treatment when living

in their own homes. . . . As a consequence, the outlook for these unfortunates has been materially improved. Friedrich thus records that of 700 cases of early tuberculosis that were treated in this manner the disease was arrested or the patients much improved in 51 per cent. of the cases. Similar results have been reported from other sources."

That over half of the cases of tuberculosis (taken, we will assume, by and large) should have been arrested or much improved by any method of treatment is a better showing, so far as the writer knows, than has ever been made by any sanatorium, where the patients have been properly followed up and their ultimate fate ascertained. And as all sanatoria select their cases with considerable care, rejecting in some instances, as Dr. Trudeau tells us in his delightful autobiography, five-sixths of all the applicants, their figures must be judged accordingly; and, inasmuch as they claim only one-third of arrests in all their cases, the advantage of using tuberculin seems indisputable, as Simon said in the passage just quoted.

The enormous amount of good which the sanatoria have accomplished in showing that tuberculosis is curable, as no one believed fifty years ago, we thankfully acknowledge. That, however, a large percentage of consumptives cannot possibly have the advantage of sanatorium treatment is but too obvious. The general plan of tuberculin dispensaries with good follow-up work, the systematic testing of practically all children for the detection of tuberculous infection, and the training of a large corps of tuberculin experts and good and efficient nurses for follow-up work, have at last brought within sight the conquest of the great white plague.

LESIONS OF THE POSTERIOR URETHRA: THEIR SYMPTOMATOLOGY, DIAGNOSIS, AND TREATMENT.

By ERNEST M. WATSON, A.M., M.D.,

BUFFALO, NEW YORK.

THE lack of adequate recognition and employment of proper therapeutic measures in lesions of the posterior urethra is still surprisingly general. Individuals presenting symptoms that direct attention to the deep urethra, and in whom the objective findings confirm the cause of their trouble comprise a very appreciable number of the male patients seen by either the general practitioner or the man doing exclusively urological work. Oftentimes the duration, discomfort, and gravity of the symptoms bear no direct relation to the size and extent of the lesion found, and, in turn, relatively simple but well-directed efforts to relieve may bring about marked alleviation of symptoms and unquestioned cures in many instances. As a class, these men form a group of the most appreciative patients when relief is obtained, for they not infrequently have borne with physical discomfort and mental unrest for long periods of time. The routine use of the microscope, the cysto-urethroscope, and the endoscope has done much to bring the study and therapy of these conditions under a clearer light, and to establish them on a plane of definite entities where they can be handled in a logical, approved, and scientific manner.

Perhaps the most common pathological condition met with in this group is a catarrhal inflammation of the posterior urethra. This very often follows an acute anterior urethritis caused by the diplococcus of Neisser, by any of the large group of staphylococci or pyogenic organisms, or by other extraneous bacteria which may be introduced or find their way into the urethra, and through trauma, lowered resistance, and their large numbers grow there. Symptomatically a slight burning about the neck of the bladder with a feeling of soreness and tenderness, though not acute, associated with more or less urinary frequency, ushers in the progress of the infection as it passes posteriorly beyond the anterior layer of the triangular ligament. Objectively the urine becomes generally cloudy in the three glasses voided, where previously when the anterior urethra only was involved the first glass specimen was cloudy and the second and third glasses relatively clear. Microscopically pus cells are found in large numbers in the centrifuged specimen from the third glass, and early in the infection the offending organisms may be demonstrated in the stained smear from the third glass, though they frequently cannot be found after the infection has persisted for some time.

In these cases irrigations with the silver salts have universally proved the most beneficial. A ten per cent. solution of silver nitrate, of which 6 to 10 drops are added to a quart of warm sterile water, forms a most suitable medium for irrigation. In the absence of a urethral discharge this may be allowed to flow back under pressure by gravity past the two sphincters into the bladder and then voided by the patient, in this manner the bladder, posterior, and anterior urethra are thoroughly washed. Dakin's solution 1:1000 has not been found by the writer to possess any advantage over silver nitrate, and, in fact, it seems less efficient in rendering the urethra germ free. After irrigation the instillation of a half ounce of 10 per cent. argyrol by means of a bulb syringe into the posterior urethra and bladder, this solution to be retained by the patient for 1 or 2 hours, if possible, is an excellent proceedure.

With every posterior urethritis there is always a certain amount of inflammation in and about the prostatic ducts, of which there are many opening along the prostatic urethra. According to Lowsley[1], who has studied many autopsy specimens in serial sections, these ducts number 50 or 60 and are considerably more numerous than has been generally supposed. The resulting inflammation of the prostate gland itself from this infection is a variable matter. With the clearing up of the urinary infection, as noted in the three glass specimens with microscopic studies from the third glass, the degree of prostatic involvement may be accurately determined. When the prostate becomes involved there may be at first no definite symptoms if the infection is of low grade. After a time, a feeling of discomfort may be noted characterized by a slight, dull ache about the neck of the bladder, with intermittant smarting and burning, sometimes associated with urination, but sometimes not so described. Occasionally there are periods of increased frequency of urination, with a dull ache localized by the patient between the rectum and urethra. In the more

advanced cases a moderate backache, frequently termed by the individual a "lumbago," with occasional pains down the legs, is noted.

Per rectum the palpation of the prostate reveals a certain bogginess and lack of elasticity with more or less diffuse firmness which is characteristic of an inflammatory process. The gland is thus rather generally indurated and about it are adhesions which render it more fixed than normal, and attempts to determine its mobility elicit more discomfort than is normally the case. The prostatic secretion in these cases, when examined microscopically, shows an increase in the number of pus cells present; normally about 2 to 3 per cent. as estimated in relation to the number of lecithin bodies found, in inflammatory conditions they may frequently reach as high as 50 to 60 per cent., with no appreciable change in the number or character of the other constituents of the prostatic secretion.

In the therapy of chronic prostatitis massage of the gland per rectum has been found to yield highly satisfactory results in the true inflammatory and also in the congestive conditions. The massage should not be violent and should be done in a circular or rotary manner over several selected areas on each side, rather than by a stroking or rubbing movement. Following this, a deep urethral irrigation of a weak solution of nitrate of silver and an instillation of argyrol are of benefit. In the more resistant cases with no organisms present, periodic dilatation of the urethra with the Kollman anterior-posterior dilator is a decided aid in opening the prostatic ducts. In certain sensitive conditions the deposition of strong solutions of argyrol into the prostatic urethra by means of the deep urethral instillator is of unquestioned benefit.

Of more or less coincident occurrence, though of less frequent clinical recognition in infections of the posterior urethra and prostate, are the various infections of the seminal vesicles. The openings of the ejaculatory ducts, situated as they are on either side of the verumontanum within the posterior urethra, are frequently with their lymphatics the path of entry for a persistent inflammation in the vesicles themselves. The symptoms of vesicular infection are varied. In one group there is slight urinary frequency, occasional smarting and burning on voiding with an uncomfortable feeling between the rectum and bladder. These cases usually have some prostatitis and which symptoms are essentially vesicular in distinction to those that are prostatic it is difficult to say. Another group comprises those with no urinary symptoms but with joint involvement, indicating that the vesicular condition is simply a focus of toxemia or bacteriemia which keeps up the arthritis. A third group embraces those with a bacilluria or a pyuria or both as presenting symptoms, occasionally with fever and rarely with recurring epididymitis, but with practically no other urinary or generalized symptoms. The diagnosis of seminal vesiculitis is not always easy and it may be said to be arrived at largely through the elimination of other possible foci along the urogenital tract. After massage of the prostate and thorough irrigation of the posterior urethra, the vesicles can be examined per rectum. In certain inflammatory conditions they are found to be enlarged and definitely indurated, making their consistency more firm and less resilient than normal. Also the amount of perivesicular adhesions may be increased as determined by the thickening about them and too by their "fixedness" to the posterior bladder wall and upper border of the prostate. The degree of adhesions also alters their position somewhat and frequently they are drawn outward toward the pelvic walls. In some cases, however, there are practically no abnormalities noted in the palpation of the vesicles per rectum, particularly in the older cases in which several years have elapsed since their initial infection. The vesicular secretion may be obtained after urethral irrigation by gently stripping the vesicles by the finger from their tip inward and downward toward the ejaculatory ducts, the secretion being obtained as it emerges from the meatus for microscopic study, care being taken not to press the prostate during this maneuver. In cases with pyuria or bacilluria as an objective finding, a possible pyelitis should always be ruled out by ureteral catheterization and microscopic studies of the urine from the separate kidneys.

In the care of inflammatory conditions of the vesicles a course of vesicular emptying through massage per rectum and deep urethral irrigation followed by instillations of argyrol should always be advised before anything more radical is advocated. When the vesicles have been definitely established as foci of infection their injection through the ejaculatory ducts with weak solutions of argyrol (3 to 5 per cent.) or silver nitrate (0.5 per cent.) by means of Geraghty's utricle syringe may be tried. In the writer's hands, however, this method has seemed to possess no additional merit over the deep urethral instillations of the solutions. Many cases of vesicular infection will be cleared up by the above means but the more resistant ones show no improvement or at the most very little following such treatment. For these, vaccines and surgical intervention are the means at hand. Seminal vesiculotomy and partial seminal vesiculectomy, with incision and drainage of the ampulla of the vas on each side, holds out a hope of very definite value in certain suitable cases. The most benefit from this procedure has been obtained in individuals with seminal vesiculitis associated with early joint involvement (beginning ankylosis),[2] and, too, those with a bacilluria or pyuria[3] of vesicular origin.

Another group of cases the study and therapy of which is assuming in recent years a more rational basis is the one of inflammatory lesions of the verumontanum. Through the use of the modern cysto-urethroscope and endoscope it is now possible to recognize and treat this large group of conditions with great efficacy. The common lesions of the verumontanum are of two types: (*a*) the infectious inflammatory, and (*b*) the congestive. The former follows recent or old infections of the posterior urethra, at least these individuals give a history of a specific urethritis. Symptomatically these men have usually sexual disturbances, *i.e.*, nocturnal emissions more frequently than normal with at times a diminution of sexual powers. In addition, there may be present symptoms referrable to the general irritative condition of the prostatic urethra such as a feeling of pressure or fullness about the bladder neck frequently described as a "tightness" about the deep urethra. Sometimes

there is present a sensation of pain in the perineum which is occasionally referred to different sites along the penile urethra. The congestive conditions occurring in individuals who give no history of a previous urethral infection but who often give a history of sexual excesses and abuses are not much different symptomatically from the true infectious type. These occur as a rule in men of early middle life, and in addition to the symptoms of decreased sexual power (practically never emissions) and occasional pain following coitus, have also some slight urinary frequency. This last symptom, however, may be due to prostatic changes such as a "median bar" formation and in men at this time of life this condition must be ruled out by careful cystoscopic study. By means of the endoscope the lesions of the verumontanum can be studied with great accuracy and the resulting condition of the infection or congestion as evidenced by hyperemia, irregularities, and hypertrophy with also the degree of involvement about the mouth of the utricle and openings of the ejaculatory ducts may be treated most advantageously. Occasionally the dilatation of the ejaculatory ducts with suitable small probes may relieve the most annoying sexual symptoms which have persisted for years. For most hyperemic, infectious, and congestive conditions the application of a 10 per cent solution of silver nitrate through the open-air endoscope direct to the verumontanum is the most valuable remedy. The injection of the utricle with a weak solution of silver nitrate (0.5 per cent.) and at times the deep urethral instillation of the same by means of a syringe of the Keyes-Ultzmann type is also of great value. In the more irritative conditions periodic dilatation of the posterior urethra and the deposition of a suitable ointment[4] (lanolin and phenol 2 per cent) is of real benefit.

Under the term "Urethritis chronica cystica," Buerger[5] some years ago described a not uncommon lesion of the posterior urethra in the nature of single or multiple small cysts. These he believes are of two varieties, viz., those following an inflammatory process (Neisser infection), and those which are simple mucous retention cysts. The symptoms of this condition may be nil, but when present are usually a slight discharge, increased urinary frequency, and rarely pain in the perineum or along the urethra. Through the endoscope or cystourethroscope these lesions may be quickly and readily recognized by their shape, contour, translucency, and mobility. Their location may be practically anywhere between the two sphincters and frequently along the sphincteric margin of the bladder, and at times the colliculus may be involved.

Therapeutically the incision or excision of the cyst wall by means of the special endoscopic instruments or the application of the high-frequency current is usually sufficient to cause their complete destruction.

Somewhat akin symptomatically to the foregoing lesions are the benign polyps of the posterior urethra which have been described in some length recently by Randall.[6] These are essentially of the same nature as certain polyps occurring on the mucous surfaces of other portions of the body, and so far as we know are absolutely benign. A chronic discharge, some urinary frequency, occasional pains, local or referred, with not infrequently abnormal seminal emissions, but only rarely bleeding, comprise the usual symptoms. Enodscopically they are seen as typical small, rounded, pedunculated elevations covered with mucous membrane.

The most effectual and satisfactory method of treatment of these growths is the high frequency current, one application of which is often sufficient to cause the complete disappearance of a single polyp.

Of only occasional occurrence among the lesions of the posterior urethra, yet of great importance in making an early diagnosis are the congenital malformations. Examples of these reported recently by Knox and Spunt[7] and Lowsley[8] enable us to appreciate the great impotance of their early clinical recognition. These are on the order of a "valve" or membrane extending from the verumontanum to the sides of the urethra and so from birth materially interfering with urination. Individuals with such a malformation rarely live beyond the second decade because of the secondary renal impairment dependent upon the urinary obstruction with back pressure. In the case of children with great frequency, dribbling, and a palpable bladder above the symphysis, one should always consider the possibility of urinary obstruction from a congenital fold in the posterior urethra. Endoscopically the diagnosis in children is impossible, but in young adults it may be accomplished. One case of this sort (Irvin) was seen by the writer while on the wards of the Brady Urological Institute in the service of Dr. Hugh H. Young, and the "valve" removed by the familiar punch operation.[9] As a usual thing in children a suprapubic operation is advisable with thorough exploration of the posterior urethra and the removal of any constricting bands followed by continued vesical drainage (suprapubically) to try and revive the renal parenchyma impaired by long-continued back pressure.

THE SPLENIC REFLEXES OF ABRAMS IN THE DIAGNOSIS AND TREATMENT OF SYPHILIS.

By ALBERT ABRAMS, A.M., M.D., LL.D.,

SAN FRANCISCO, CAL.

THE heart and lung reflexes of Abrams are familiar to the average clinician but little is known of the splenic reflexes despite their importance in diagnosis and treatment.

The Spleen.—This enigmatical viscus of the physiologist contracts and expands synchronously with the digestive periods. In its contractions it loses 18 per cent. of its volume. The volume changes are akin to the peristalsis of the gastrointestinal tract and are caused by rhythmic contractions of the smooth muscle tissue in the capsule and trabeculæ. It is the popular belief that the spleen is influenced by the nervous system and Botkin asserts that depressing emotions increase and exhilarating ideas diminish its volume.

Tumefaction of the spleen occurs in practically all acute infectious diseases.

Splenic Reflexes.—The visceromotor centers in the cord may be stimulated so that one may at random either contract or dilate the spleen. These reflexes* are known respectively as the splenic reflex of contraction and dilatation. In the norm, the reflexes are of short duration (not in excess of 2 minutes), and, in their objective demonstration by radiodiagnosis and percussion, one must expedite the latter maneuver. It has been determined empirically that the elicitation of the reflex of contraction is effected by concussion of the 2nd lumbar spine and the counter splenic reflex of dilatation by concussion of the 11th dorsal spine. An ordinary percussion hammer and pleximeter suffice to evoke the reflexes. The pleximeter is placed on either spinous process and then struck a series of moderately vigorous blows with the plexor.

Reflexodiagnosis and Reflexotherapy.—The reflex of contraction is employed in the treatment of splenomegaly.

In latent malaria, one may precipitate a typical paroxysm by discharging the splenic reflex of contraction (concussion of the 2nd lumbar spine). It is assumed that the paroxysm is provoked by the mechanical extrusion into the circulation of the plasmodia which have lodged in the organ.

In suspected malaria, one may find plasmodia in the blood after evoking the reflex of contraction even though absent before this maneuver is executed. Hematological investigations by the writer show the following: (1) Average increase of erythrocytes after concussion of the 11th dorsal spine (which increases the splenic volume), 300.000 and an average increase of hemoglobin of 5 per cent.; (2) average leucocyte increase after concussion of 2nd lumbar spine (decreases splenic volume), 2.800; (3) average increase of red cells after alternate concussion of 2nd lumbar and 11th dorsal spines, 650.000 with an average hemoglobin increase of 10 per cent.

Diagnosis and Treatment of Syphilis.—The frequency with which the writer encounters syphilis by aid of the electronic reactions of Abrams,* emphasizes the dictum of Fournier—general pathology should be made a mere annex to syphilography.

In congenital syphilis where the reaction may be absent in the blood, it may be invariably elicited from the same fluid after evoking the splenic reflex of contraction. It has occurred to the writer that evocation of the reflex in question might be of value in the serological diagnosis of syphilis. In his earlier investigations this was apparently true relative to the Wassermann test but subsequent tests with a larger number of patients did not justify this conclusion.

The Noguchi reaction, however, was modified as shown in the following tabulation, which practically summarizes many investigations:

	Noguchi reaction from blood before elicitation of the splenic reflex of contraction.	Noguchi reaction from blood after elicitation of the splenic reflex of contraction.
Case 1 =	—	+
Case 2 =	+	++
Case 3 =	++	+++
Case 4 =	+	+++
Case 5 =	+	+++
Case 6 =	—	++
Case 7 =	+	+
Case 8 =	+	+++
Case 9 =	—	—
Case 10 =	+	+++

After the blood was removed with the trocar in the vein, it was occluded by the finger and the 2nd lumbar spine was concussed for one minute, after which a second specimen of blood was allowed to flow.

The recognized uncertainty of the Wassermann is no doubt due to the fact that it is not dependent on syphilitic antibodies in the blood, but upon admission to the latter of abnormal products from morbid tissues.

After careful investigations, the writer has learned to recognize the value of eliciting the splenic reflex of contraction in the treatment of malaria in connection with its specific drug.

Laveran avers that the plasmodia find protection in the spleen from destruction in the circulation. In every case of suspected malaria, if elicitation of the splenic reflex of contraction does not cause a malarial paroxysm or some atypical evidence of the same, experience has taught me to exclude malaria. Furthermore, I have never permanently cured a case of malaria until the splenic reflex of contraction was employed in conjunction with quinine. We have shown that the splenic reflex of contraction causes a leucocytosis. Experimentally, it has been demonstrated that intravenous injection of splenic extract evokes a like condition. Wells has shown that the splenic pulp contains the greatest number of leucocytes. This concentration is evidently the result of the fixation in the spleen of morbid products which exert a positive chemotactic influence toward the leucocytes. Evocation of the splenic reflex of contraction is a valuable treatment for all infections.

Conclusions.—1. The usual depositories for the

*More fully described in Abrams' "Spondylotherapy," fifth edition, pages 351 *et seq.* and in the "Reference Handbook of the Medical Sciences," Vol. VII, third edition.

*Abrams' New Concepts in Diagnosis and Treatment, 1916, and *International Clinics*, Vol. 1, 27th series.

luetic virus are the spleen and liver, notably the former.

2. When the splenic and hepatic reflexes of contraction are evoked by the same maneuver (concussion of the 2nd lumbar spine), there is an immediate extrusion of the virus into the circulation.

3. Emotions, digestive disturbances, and other factors, by precipitating volume changes in the spleen, eliminate the virus of syphilis, causing an exacerbation of symptoms present or producing them if absent.

4. In parasyphilitic diseases, so called, the parasites are found in the "dead corners" of the organism and resist drug action. Similarly, virus lodged in the spleen is equally resistant. Elicitation of the splenic reflex is, therefore, a valuable adjunct in syphilotherapy.

THE NECESSITY OF FURTHER ADMINISTRATIVE CONTROL OF SCALP DISEASES IN CHILDREN AND ADULTS.

WITH OBSERVATIONS ON THE RETAIL HAT TRADE.

By WALLACE A. MANHEIMER, Ph.D.,

NEW YORK.

SECRETARY AMERICAN ASSOCIATION FOR PROMOTING HYGIENE AND PUBLIC BATHS.

The object of this paper is to draw together certain data on the incidence and importance of skin diseases for the purpose of urging greater effort in the administrative control of such infections. As regards the incidence of skin infections among the general population, few positive data are available. For the reason that most of such diseases are not reportable, their incidence can be only estimated from the reliable statistics in the army and navy and from those obtained in the physical examination of schoolchildren. As regards the importance of further administrative control of skin infections, we believe that an inquiry into the causes of loss of time of pupils from school and damage to the personnel of the army or navy will demonstrate the value of increased emphasis on those measures calculated to prevent the dissemination of such maladies.

The large number of infections included under skin diseases has made it desirable to confine this discussion primarily to diseases of the face and scalp, particularly in view of their more frequent incidence and of the greater promise of success to the measures proposed for their control.

Pediculosis Capitis.—In the report of the Director of Child Hygiene of the Department of Health, New York City (Dec. 31, 1910), out of a total of 266,426 examinations, 153,797 cases of pediculosis were found, comprising nearly 59 per cent. of the children examined. In the report of the Head School Nurse (Philadelphia, 1910) out of 13,659 physical defects observed, 4,556 were cases of pediculosis comprising over 33 per cent. of the incidence of disease observed. As a cause of loss of school time, out of a total of 6,960 days lost for all causes in one school, 1,830 days were lost through pediculosis, whereas only 34 days were lost on account of diphtheria and contact with diphtheria, 60 on account of scarlet fever and contact with scarlet fever, 132 on account of measles, 380 on account of varicella, 85 on account of pertussus, or a total of 691 days lost on account of the epidemic diseases and contact with them as against 1,830 lost from pediculosis alone! If we add to the time lost from pediculosis that lost from the other scalp diseases, a really strong case is presented for the greater administrative control of such infections.

That pediculosis is not confined to school children but is pretty well distributed in the adult population is quite well known. It is one of the most frequent conditions observed in the admitting rooms of all hospitals. It is one of the most prevalent conditions met with in the physical examinations of recruits for the army and navy. Among less than 10,000 graduates of high school examined prior to entrance to college, during a period of 5½ years, 2,548 were infected with head lice. The incidence of this disease (or of any other) among high-school pupils generally in New York City is not known because the students are not given the benefit of periodical physical examinations. The experience of physical instructors in the high schools indicates the really enormous importance of the introduction here of a routine of physical examinations.

The well-known etiology of typhus fever (Brill's disease), which is spread by head lice (Anderson & Goldberger) as well as by body lice, and the almost ubiquitous incidence of this infection indicates the desirability of a more general concern for the suppression of lice. It is generally and probably correctly believed that many cases of Brill's disease pass unrecognized, receiving an incorrect diagnosis, and that the incidence of this malady is much greater than supposed. The disease, furthermore, is on the increase, and with the return of our troops at the close of the war, it is not unreasonable to suppose that the more virulent type (European typhus fever) will be introduced into our country.

The Syphilides.—The incidence of syphilis in the general population is variously estimated by the different authors from between 3 and 30 per cent. The opinions of the leading syphilographers in this country establishes 10 per cent. as the incidence of syphilis in the United States. Although the vast majority of syphilitics acquire the disease through sexual intercourse, a considerable number of infections are innocently acquired, as demonstrated by the large number of cases of extragenital chancres reported in the literature.

D. W. Montgomery (*Jour. Cut. Dis.*, 1905, p. 342) gives a table of the percentage of the occurrence of extragenital chancres to all chancres as observed by various authors both here and abroad. The table follows:

	Per Cent. of extragenital chancre.
Montgomery (California)	5.5
Krefting (Christiania)	15.6
Fournier (Paris)	9.0
Broich (Bonn)	9.0
Van Walsen (Amsterdam)	8.5
Mracek (Vienna)	7.5
Bulkley (New York)	5.5
Finger (Vienna)	1.3

In Russia, Metchnikoff has stated, from 75 to 80 per cent. of all chancres are extragenital, due, not

to perversion of sex, but to insanitary and unhygienic practices generally.

The course of extragenital chancres is short and usually mild, and it is fair to assume that the majority of patients with this malady never consult a physician at all. Indeed, Pellizzari states that the physician sees only 1/10 of such cases. Consequently when secondary syphilis breaks out, the physician often erroneously ascribes the cause to sexual intercourse. Montgomery, summarizing his experience and that of Bulkley, states that at least 10 per cent. of all syphilis in this country is extragenitally acquired.

In the United States, therefore, if we accept the foregoing figures, 10,000,000 individuals are infected with syphilis, one million of whom became infected innocently. New York City has a population of 600,000 syphilitics, 60,000 of whom acquired the disease out of venery. If these facts were emphasized in our campaigns of public-health education, the lay disapproval attaching to the proper administrative control of syphilis would vanish.

Since the later stages of syphilis almost invariably result in skin lesions (the syphilides) the previous discussion properly falls within the realm of this paper. The pustular syphilides, while they attack any portion of the integument, are most marked on the scalp, forehead and face. "Acne syphilitica" and "impetigo syphilitica" represent forms of unusual importance in this connection. The *Treponema pallidum* is present in the discharges from the pustules and the dissemination of such matter from one person to another must occur in numerous ways. We will refer later to a hitherto entirely neglected mode of transference of scalp diseases in the retail hat industry, but before advancing to the other details of this paper it is well to remark that of the vast majority of syphilitics presenting skin lesions, many present lesions of the forehead and scalp. We submit that the trying on of hats by such individuals is a mode of transmission of syphilis which is entitled to administrative control not only because of the seriousness of the malady but because of its widespread prevalence.

Miscellaneous Diseases.—In order not to prolong this paper unduly we will group together a few more scalp diseases and discuss them briefly. *Acne* is an exceedingly common malady, the discharges from the pustules of which contain infective organisms (*Staphylococcus albus*, streptococci and possibly Gilchrist's bacillus of acne (?)) which are frequently transmitted to individuals fitting hats. While this disease is considered to be constitutional in origin, the facts of its widespread occurrence and location on the face, argue for the suppression of the modes of dissemination of its infectious discharges.

Impetigo Contagiosa.—In New York City out of 266,426 children examined, 9,052 showed impetigo contagiosa. In Philadelphia, out of 6,960 days lost from all causes (in one school) 432 were lost on account of this disease.

Ringworm represents another common affliction. Out of 266,426 children examined (New York report) 4,805 children were infected. In Philadelphia, in one school 448 days out of a total of 6,960 were lost on account of this disease.

Leprosy is a disease which is considered to be on the increase in this country. S. Pollitzer (*Jour. Cut. Dis.*, 1916, Vol. 34, p. 55) claims that there are between 500 and 1000 unrecognized cases in the United States, and that the number is gradually increasing. Cases are being admitted to the great ports constantly. He states, "The state of New York virtually ignores the disease, with the result that according to the best authorities there are probably 150 lepers in the city of New York and its environs." "The free admixture of this element of contagium among our people constitutes a menace which at any time, if we read history aright, may become imminent." Since this disease breaks out on the skin, and since it can probably be contracted through the introduction of the leprosy bacillus into fissures of the skin, its consideration properly belongs here.

Erysipelas is due to the introduction into the skin of streptococci. The infective organism, it is well known, after passage through the human being, is more infective to a second person. This disease also frequently attacks the face and forehead.

Numerous other infections, some entirely confined to the scalp, forehead, and face, and others occasionally present there, might be considered. Enough have been mentioned, however, to indicate the high degree of prevalence of such infections among the general population.

Gatewood ("Naval Hygiene," 1909) in his illuminating report on vital statistics in the navy makes the following statements: "Diseases of the cutaneous apparatus, non-parasitic and non-venereal, caused as a class about 5 per cent. of the total damage from diseased, greatly exceeding the damage from diseases of the visual apparatus and nearly equaling that from diseases of the respiratory apparatus. They were responsible for loss equal to 45 per cent. of that caused by all diseases of the nervous system, to 62 per cent. of that from all diseases of the digestive apparatus, and to more than 81 per cent. from diseases of the circulatory apparatus. They had an importance equal to 67 per cent. of that of tuberculosis and caused damage considerably greater than typhoid fever and pneumonia together." "The epidemic diseases have claimed the attention of mankind and great advances have been made in their prophylaxis but the naval record emphasizes the importance in the service of the study of diseases of the skin." "For it is the *constantly acting and often small adverse influences* that cause the greatest loss, rather than the striking and crippling effects resulting from the occasional visits of epidemic diseases." If we add to the above estimates of Gatewood, the loss and damage due to skin diseases, parasitic and venereal in origin, a really strong case is made out in favor of the greater administrative control of these maladies.

Transmissibility of Infection Through Hats.—Because of the obvious connection of the retail hat industry with the dissemination of pediculi and of all types of infectious discharges, and in the light of the prevalence of scalp infections and their importance to the health and vitality of the people, a study of infections traceable to this source was conducted.

During the height of the busy season a great many hat stores were inspected and subsequently

numerous retail hat salesmen were interviewed. While no observations could be made in the prevalence of pediculosis capitis under the conditions of the inspection, nevertheless, in the community where these inspections were made, that disease is known to be common. By actual count, over 2 per cent. of the men trying on hats had noticeable eruptions on the face or forehead, although, of course, the exact nature of the eruptions could not be ascertained.

Results of an inquiry among the hat salesmen as to the presence of lice in their own merchandise and in hats discarded by patrons, was not very satisfactory, although a number of the more intelligent salesmen admitted that they had observed such conditions. It was pretty generally confessed by all the men interrogated that no prospective hat purchaser would be denied the privilege of trying on hats, even though he exhibited noticeable discharges on the forehead. Furthermore, although the sweatbands of the hats frequently become soiled they are rarely changed, unless in very bad condition. Few hat purchasers try on less than four hats during the process of fitting, while the majority try on even more. A large proportion of the new hats, therefore, must become infected with the discharges which accompany numerous forms of scalp and skin diseases.

In the better class stores a head conformator is used so as to shape the hat properly on a block. This head conformator is used on all customers and must of necessity become contaminated. This has already been recognized by the hat trade, and accordingly in the better class stores small paper scull caps have been provided for the protection of the head. It was found that these skull caps do not interfere with the fit of the hat and for this reason the high-class establishments have provided their customers with skull caps to be used while fitting on hats in addition to their use with the conformator. The skull cap is made of paper, and is consequently so cheap that it can always be discarded after individual use.

Unfortunately, this practice is at present confined to high-class establishments, although the need of it in the poorer class of store is notoriously much more urgent.

When the common drinking cup was abolished it took years to get the public used to the desirability of individual drinking cups. One of the most important results of the abolishing of the common drinking cup has been the educating of the public to the mode of transfer of diseases through saliva. May not a provision requiring the general application of paper skull caps while fitting hats have a similar educational advantage? Is it not proper to obtain for the poor people by law what is gratuitously provided for the better class of people in the community? We believe that the prevalence and importance of scalp and face diseases makes imperative the promulgation of an ordinance requiring the providing of paper skull caps and their use by the people. The trifling cost of the article (it being less than 0.5 per cent. of the average cost of the hat) would amount to practically nothing compared with the benefits derived. The salutary and educational results of such an ordinance should be sufficient reason for its enactment.

THE TREATMENT OF LOBAR PNEUMONIA.

By M. FORD MORRIS, JR., M.D.,

CHELSEA, MASS.

RESIDENT PHYSICIAN, SOLDIERS' HOME HOSPITAL.

With the approach of winter, it is advisable that we take an inventory of the agents in our remedial armamentarium for combating lobar pneumonia. In taking stock of such agents, we find that we have saveral very useful means of treating this most fatal of the acute infectious diseases of temperate climates. In the sense that quinine is specific in malaria, or thyroid extract in myxedema, there is yet no specific remedy in the treatment of croupous pneumonia. However, the profession is making progress in the search for such a specific.

In prescribing any form of treatment, it is absolutely necessary to keep in mind the fact that this is an acute infectious disease, caused usually by the pneumococcus, whose chief local manifestation is a consolidation of more or less pulmonic tissue, and which is accompanied by pyrexia and toxemia, the latter of which has a specially harmful action on the cardiac muscle. For convenience, the treatment may be considered under several subdivisions, as follows:

1. Prophylactic.—All measures which keep individual resistance at a high level will help to prevent pneumonia. Good food, plenty of sleep, an abundance of fresh air, proper clothing, a cool sponge bath every morning, are excellent prophylactic measures. The very young, the very old, and anyone with impaired resistance, especially those having respiratory or cardiac lesions, should not be allowed to visit patients having pneumonia. Nurses, or other attendants upon pneumonia cases, should have everything mentioned in the second sentence of this paragraph. The sputum of a patient should be expectorated into a sputum-cup or other receptacle containing 1-20 carbolated water; it is advisable to empty such a cuspidor several times daily and to burn the sputum.

2. Hygienic.—The sickroom should be light and airy, and should contain only the most necessary articles of furniture. The temperature should be that of the outside air. The patient should not be burdened with excessive covering and should be protected from draughts by screens. The patient should have complete mental and physical rest, as well as expert nursing. The diet should consist of easily-digested, easily-assimilated, non-fermentative foods of high caloric value. Small amounts of nourishment should be given every two or three hours. The patient should be urged to drink freely of water. And he or she should have *fresh air in abundance.*

3. Symptomatic.—Hot drinks and hot water bottles will lessen the discomfort of the initial chill. The fever does not usually call for treatment. If the temperature is above 104° F., a cool sponge bath should be given. If there is any serious cardiac disturbance accompanying such fever, the warm, instead of the cold, sponge bath should be given. Tub baths have no place in the treatment of pneumonia.

The pleurisy, which almost always accompanies this disease, is best relieved by strapping the affected side, from the sternum to the vertebral column and at right angles to the sternum, with adhesive

plaster. If this does not relieve the pleuritic pain, heroin gr. 1/12 or codein gr. ¼ to ½ should be given. It is true that mustard plasters tend to lessen this pain, but "the notion that the course of an acute infective inflammation in the alveoli can be modified by doing something to the skin of the chest is pathologically untrue and physiologically impossible."[1]

The toxemia is best overcome by an abundance of fresh air and water. Water, by mouth, by the rectal drip, by hypodermoclysis, or injected directly into a vein, should be given in a quantity not less than three pints daily. For severe toxemia, Fussell[2] recommends, in addition, large doses of alcohol. An ice-cap to the head tends to lessen headache and delirium, and to promote sleep.

The lesser degree of delirium may usually be overcome by bromides in gr. xx doses q. 3 h. The severe types call for morphine in ¼ gr. doses.

Abdominal distention is best relieved by eserine sulphate or pituitrin hypodermically, terpentine stupes, and asafetida enema.

A frequent, painful cough may be relieved by either heroin gr. 1/12, or codeine ¼.

Since it is the air sacs and not the bronchi which are affected, expectorants are unnecessary. In fact, "the use of expectorants in pneumonia is, in the great majority of cases, entirely useless and often harmful."[3] However, ammonium chloride, in 5 or 10-grain doses, is efficacious in relieving a persistent bronchitis during the stage of resolution.

Drug habitués should not be deprived of their drug during an attack of pneumonia.

Cardiac Symptoms.—The pneumonia poisons produce a very harmful effect on the heart muscle. As a result, the condition of the heart usually necessitates some form of stimulation. Valvular pathological conditions which indicate the need of digitalis should have this drug,—even though the effect of digitalis, in the presence of fever, and upon the cardiac muscle fibers poisoned by the pneumonia toxins, is very feeble. In such patients, morphine in ¼ gr. doses has a beneficial action upon the heart.

When the pulse is fast and feeble, when the quality of the first sound is poor, or when the pulmonic second sound is accentuated, cardiac stimulation is needed. When the pulse is arrhythmic in any form and when the blood pressure, expressed in mm. of mercury, is less than the pulse rate, expressed in the number of beats per minute (Gibson's rule), the cardiac condition is very serious. Caffeine sodium benzoate is a very excellent stimulant. The compound spirit of ether and the aromatic spirit of ammonia are excellent rapidly diffusible stimulants. Camphor in oil is slower, but quite powerful. Strophanthin, given intravenously, is probably the most powerful stimulant of heart muscle known to man, but this agent should not be given following the administration of digitalis. Atrophine is a valuable agent in collapse. Only when the heart is laboring against increased peripheral resistance occasioned by the contraction of the arterioles, or when the blood pressure in an arteriosclerotic patient is ascending to unsafe levels, should nitroglycerin be given.

In empyemia, the pus should be evacuated.

4. Immunotherapeutic.—Cole and Dochez[4] have found that pneumococci are of four distince types (I., II., III., IV.), and that, so far as specific therapy is concerned, pneumonia is caused by four different organisms; that Types I. and II. are the most prevalent, and that each of these types yields a protective antipneumococcus serum, that of Type I. being much more potent. These two scientists found it impossible to treat pneumonia caused by either Type III. or IV., because in one type the organisms are of distinct varieties and the other type does not yield an immune serum. But there is much consolation in the fact that infection by either Type III. or IV. is relatively slight and rarely fatal. In all cases studied by Cole and Dochez, "the serum had an ultimate favorable effect in lowering the temperature and shortening the course of the disease." In all cases, one injection was sufficient to render the blood sterile.

The particular type of causative organism is determined by the agglutination test or Blake's precipitin test[5] on a culture obtained either from the blood, sputum coughed from the lung, or directly from the lung by means of a needle inserted into it. If the causative organism belongs to either Type I. or II., the treatment, with the appropriate serum in doses of 50 to 100 c.c. diluted one-half with normal saline solution, injected into a suitable vein, is begun immediately. The condition of the patient is used as a guide to further treatment. The total amount of serum used is from 190 to 700 c.c., and the dose should ordinarily not be repeated within 12 hours of the preceding one.

"The status of vaccination in pneumonia, both prophylactic and curative, is still very doubtful—and the evidence of clinicians in favor of vaccination as a therapeutic measure is insufficient to overthrow the general scientific arguments against the procedure."[4]

Hiss[6] reports very good results in the treatment of pneumonia with an extract of leucocytes obtained from rabbits, in doses of 20 to 60 c.c q. 4 h.

5. Chemotherapy.—At the present time, quinine and its derivatives are the nearest approaches to a specific chemical remedy. In 1901, Petzold[7] used quinine hydrochlorate hypodermically and considered it a specific. Later, Henry[8] enhusiastically reported using quinine hydrochlorosulphate on account of its greater solubility, hypodermically.

In 1912, Cohen[9] reported his use of a 50 per cent. solution in water of quinine and urea, given into the muscles, in doses totalling 90 to 150 grains within 48 to 60 hours, without cinchonism. As a result of this form of treatment, the symptoms are favorably changed, but the physical signs are uninfluenced. In a later paper,[10] this same author asserts his belief that quinine and its congeners are antitoxics or antidotes to the pneumococcic toxins; that often one dose is sufficient to insure recovery. In other cases, however, he says that the quinine and urea must be supplemented by heart stimulants. When the temperature is over 103° F., he gives, either orally or intramuscularly, 7½ to 15 grains every 3 hours until the temperature is reduced to 102.2° F. Commenting on this quinine and urea treatment, Billings[11] says the effect is solely from the quinine, which, if given in sufficiently large doses, will lower febrile temperature, but advises against combating high temperature in pneumonia with antipyretics.

At present ethylhydrocuprein, a synthetic quinine-like substance, seems to be the best chemical agent in treating lobar pneumonia. Ethylhydrocuprein was probably first used by Morgenroth and Levy[12] while they were working with various derivatives of quinine. Cole[13] says that this substance is 150 times as strong as quinine, and that it has the power, even in the dilution of 1 to 5,000,000, of killing pneumococci in the test tube, and that it seems to be effective against all types of pneumococci.

Both Wright[14] and Frankel[15] noted several cases of transitory amblyopia following its use, and the former was unable to observe any therapeutic effects whatever. Also Stuhmer[16] has reported a case of transitory total amaurosis following a total of 2.25 grams administered within 48 hours. These ill effects are probably due to the facts that the therapeutic dose is very near the toxic dose, and that these patients received too large a dose.

In a series of 20 cases, Becher[17] obtained most excellent results. He found that, when the drug was begun on the first day of the disease, the average time until the disappearance of fever was 2½ days; when begun on the second day, it was a little over 3½ days,—the time growing longer the later in the disease the administration of the drug was started. In addition to the prompt reduction of fever, Becher notes that the drug lessened the number and frequency of complications and averted serious cardiac manifestations. The untoward symptoms affect the eyes and ears particularly, and sometimes manifest themselves in nausea and vomiting.

Baerman,[18] who gave the drug in an oily suspension, thinks that this agent has an unmistakable curative action in pneumonia, especially when combined with immune serum.

Chesney[19] declares that a bactericidal action for pneumococci can be secured in the blood stream of patients if the patients are given 0.024 gram of ethylhydrocuprein per kilogram of body weight, per 24 hours. If at first a large dose is given and followed, at intervals of not more than 3 hours, by smaller doses, the appearance of this bactericidal action may be hastened.

Both Chesney and Cole recommend an initial dose of 7 or 8 grains, followed every 2 hours by 2½ grain doses. Becher gives 4 grains every 4 hours. The oral administration of the hydrochloride has given the best results.

SEVENTEEN CASES OF GOITER TREATED WITH INJECTIONS OF CARBOLIC ACID, IODINE, AND GLYCERIN.

By JOSEPH EASTMAN SHEEHAN, M.D.,

NEW YORK.

INSTRUCTOR IN DISEASES OF THE NOSE AND THROAT IN THE NEW YORK POST-GRADUATE MEDICAL SCHOOL AND HOSPITAL; CONSULTING EAR SURGEON, PORT JERVIS HOSPITAL, PORT JERVIS, N. Y.; ATTENDING EAR AND THROAT SURGEON, ST. MARY'S HOSPITAL, ORANGE, N. J.

I HAVE treated seventeen cases of goiter; seven were private patients and the remaining ten were treated at the various hospitals with which I am associated. All were in females. Of the seven private patients four were young women ranging from seventeen to twenty-five years old, who suffered with the ordinary enlargement of the thyroid gland without appreciable symptoms of thyrotoxicosis. They sought relief for the swelling of the neck only. Five injections at five-day intervals sufficed to effect a cure. The fifth case was that of a Sister of Charity, forty-seven years old, who suffered with an enlargement of the neck (goiter) for five years, and its swelling was so large that it produced some compression of the trachea, thereby causing embarrassment of breathing. She was injected over a period of a year at infrequent intervals, with the result that to-day the gland has quite subsided. Fifteen injections in all were given. Throughout the course of the treatment repeated uranalysis showed a percentage of sugar ranging from 0.5 to 4 per cent.

The sixth case was in a woman thirty-two years old, who suffered from swelling of the throat (goiter) for two years. She experienced difficulty in swallowing, particularly during the menstrual state. After seven injections, at five-day intervals, the enlargement of the gland entirely subsided and the dysphagia disappeared.

The seventh patient was an English woman who came here from London. I saw her February last. She was pale and anemic, and her breathing was greatly embarrassed; particularly was this true on exertion. A uranalysis showed 8 per cent. sugar with a high specific gravity. A nodular goiter, such as Kocher speaks of, obtruded itself on the right side of the neck, and there were evidences of the gland being cystic on the other side, with extension under the thorax, which she says began six years ago. There was not much evidence of thyrotoxicosis, the difficulty in breathing being the principal symptom, which was due to the compression of the trachea by the enlargement of the gland. Throughout a period of three months, injections at intervals of from five to eight days reduced the gland greatly until she left the city in May for the country, entirely relieved of the urgent symptoms. The reduction of the gland was so great the normal lines of the neck were clearly evident. The last uranalysis showed it to be free from sugar.

Of the ten cases treated by me at the hospitals all the patients were under twenty-seven years old, except one who was thirty-seven years old. Eight of these cases were of the ordinary enlargement of the goiter which is ordinarily found in young women.

Of the eight cases, five were entirely relieved with five injections at intervals of five days; two were greatly relieved with eight injections at intervals ranging from five to eight days; one is still under treatment, and is greatly relieved after eleven injections.

The ninth case was that of a woman twenty-two years old, who suffered from a diffuse enlargement of the gland, and who, after ten injections, covering a period of ten weeks, showed no appreciable effect in the reduction of the gland. Subsequently she was operated upon, and two days later died.

The last of the series of ten was a typical case of Graves' disease, with marked symptoms of thyrotoxicosis. I was rather loath to inject her, but as a matter of experimentation I started the treatment. To my great surprise, after the third injection the gland began to get smaller. The protrusion of the eyeballs began to recede, but the tachycardia still persisted. After the twelfth injection, covering a period of over two months, the enlargement of the gland has been very much reduced in size and all symptoms of Graves' disease have been greatly minimized, and the patient says the only thing she complains of now is palpitation of the heart and a sensation of nervousness upon forced exertion.

Method.—Five drops of equal parts of carbolic acid, C. P., tincture of iodine, and glycerin, are injected into the most prominent part of the goiter, usually at five-day intervals. In many of the cases five injections suffice, particularly in the ordinary enlargement which occurs in young women where there is no evidence of toxin absorption. If five injections do not suffice, many more can be given with perfect safety.

Action.—The object of the treatment is to cause a sclerosis of the gland, thereby modifying the abnormal function of this organ and alleviating any pressure symptoms which may be produced by the enlarged gland.

Carbolic acid and tincture of iodine cause an inflammatory reaction in the gland, followed by cicatricial adhesions and consequent obliteration of the cells. Glycerin is used as a solvent. After the injection the patient complains of pain and swelling, the pain of which terminates into soreness after twenty-four hours. If the swelling and pain continue, codeine in small doses, with ice applied over the goiter, will promptly give relief.

Conclusion.—1. Enlargement of the thyroid gland, particularly that form occurring in young women, can be cured, or at least the symptoms of the enlargement can be greatly minimized, by these injections.

2. No untoward symptoms have been observed by me from the injections. Neither is there any bad after effects from reducing the enlargements of the gland by this method.

3. Although only two cases of the graver forms of goiter have been injected with goodly effect, still the number of cases injected have not been sufficient to draw any conclusion in the efficacy of the treatment of these forms by this method. Certainly it is worth while trying in these severe forms, particularly so when the case is not a fair surgical risk.

4. It is well, when injection treatment is started, to combine it with a course of arsenic and with some form of the phosphates.

My method is as follows: Five drops of Fowler's solution is given in half a wineglass of water, three times a day—after eating each meal—for one week; then ten grains of calcium glycerophosphate is given for one week, alternating each one every week throughout a period of from eight to ten weeks.

24 East Forty-eighth Street.

REPORT OF FIVE CASES OF ACUTE STREPTOCOCCIC INFECTION.

By EDMUND G. ZIMMERER, M.D.,

LINCOLN, NEBR.

THE following case reports are interesting because they represent the large class of cases which are often unrecognized and which are diagnosed as rheumatism, grippe, etc., many times to the detriment of the patient.

CASE No. 430.—Female, æt. eight years, a patient of Dr. W. O. Colburn. Illness came on suddenly with a chill and high temperature, sore throat and joint pains. A culture from the throat grew streptococci. About the fourth day a mitral murmur was heard and the urine showed albumin and a few granular casts. Treatment consisted of salicylates and alkalies. The patient made a rapid and good recovery.

CASE No. 563.—Male, æt. 15. Had a chill in the night. Next day he developed a sore throat. Temperature 103.5 . On the following day his face was so puffed up that nephritis was suspected. Uranalysis showed a great amount of albumin and some hemoglobinuria. No casts. His nose bled and he complained of pain in the abdomen, which was somewhat distended. The temperature remained high and the following day he developed erysipelas. After this cleared up the patient passed from our observation and nothing can be said as to the outcome of the kidney affection.

CASE No. 440.—Male, æt. 16, was seen April 10. He complained of cold, chills, sore throat, and pain in the left shoulder. Temperature 103.5°, pulse 100. Chest negative, some abdominal distention. Culture from throat grew streptococci. Under salicylates the temperature came down and the symptoms improved to some extent. On the third day, however, the temperature rose to 104° and a roughened pulmonic second sound was noticeable. Urine was normal. On the fourteenth moist rales were heard over the base of the left lung, with a distinct increase of roughening of the heart sounds over the pulmonic area. He complained of pain in the shoulder and of abdominal distress. Next day there was consolidation of the lower lobe of the left lung, whispered broncophony, respiration 32, temperature 104°; white cell count 12,000. The lung cleared up promptly but the temperature continued high. On the twentieth he complained of pain in the shoulder and great tenderness over the head of the humerus. A diagnosis of acute periostitis was made and the joint was aspirated by Dr. Orr. The temperature dropped to 99° within twelve hours and he made an uneventful recovery.

CASE No. 150.—Female, æt. 2, was seen by Dr. Colburn February 28, after an illness of ten days, the history of which illness was suspiciously like that of scarlet fever. Patient had just had a convulsion. Temperature 104°, pulse 130, respiration 54. She was apparently unconscious, was restless and moaning. Examination revealed a consolidated right lung and a bulging of the drum membrane of the left ear. Para-

centesis was done and the following day the temperature was lower. The child refused all food and did not seem to notice anything. Spinal puncture was done and the examination of fluid was negative. Blood count showed leucocytes 12,000, reds normal. March fourth she became rational, took food and seemed in every way improved. Uranalysis at this time showed albumin but no casts. On the eighth albuminuria persisted, the temperature rose to 102° and the patient was becoming more restless. A waxy color at this time suggested another blood count, which showed hemoglobin 50 per cent. and red cells 3,000,000. Hypodermoclysis was instituted and the pulse improved. On the following day a transfusion was done by Dr. Hohlen and the patient reacted splendidly. The temperature rose to 104° but dropped in a few hours to 101°. On the thirteenth the temperature was normal and the pulse good. She took fluids eagerly. Red cell count was 3,500,000. Urine showed a trace of albumin. On the 14th a complete anuria began which persisted in spite of treatment and the patient died the following day. In this case the streptococcus could not be isolated from the throat or blood.

Case No. 395.—Female, æt. 18. Attended the case just cited during the last days of her illness. On March twenty-third she awoke with a severe chill, backache, and sore throat. Temperature 104°, pulse 120. Culture from the throat and later from the blood gave a growth of hemolytic streptococci. Uranalysis showed albumin but no casts. Leucocytes 7000, red cells normal. On the twenty-fifth the temperature rose and a mitral murmur was heard on auscultation. On the twenty-sixth she complained of pain in the right elbow joint. Temperature 102° and the patient was delirious. This delirium increased next day and the temperature rose to 105.5°. Albuminuria less marked but the urinary secretion was scanty. On the twenty-ninth there was marked abdominal distention of which she complained greatly. The blood count showed 15,000 leucocytes. She passed sixteen ounces of urine in twenty-four hours. The pain in her elbow increased. April first she was removed to the hospital where Drs. Orr and Hohlen drained the joint. A pocket of serum was found along the ulna. Drainage was inserted and the arm put up in plaster. She improved in every way until April 10, when an inflammatory spot was noticed over the middle of the tibia. This became worse and the other symptoms were aggravated until April 20, when an incision was made over the tibia and a quantity of pus drained therefrom, after which the temperature became normal. On the thirteenth another incision was made over the ulna, but no pus was obtained. Next day she complained of pain in the left knee, without tenderness. Blood count at this time showed red cells 5,000,000, white cells 12,000. Urine contained a trace of albumin but no casts. May 1 the blood count and uranalysis were negative. On the sixth she left the hospital and has since made a good recovery.

It is interesting to observe in these cases the marked similarity in their course. Most of them began suddenly with chills, high temperature, vague pains in the joints and all of them had sore throats. Another very constant symptom of the cases we have seen is the abdominal distention which in a number of cases gave a great deal of trouble and caused the patient much distress.

In the matter of joint involvement it will be noted that in several instances it was the diaphysis of the bone rather than the joint which was involved.

The heart in every one of these cases withstood the attack of the infection well and in no cases was there any remaining heart lesion or murmur.

The pneumonia which preceded or occurred in two of these cases is rather interesting.

Treatment in all cases consisted of salicylates in large doses, together with sodium bicarbonate by mouth, Fischer's solution by rectum, etc. Salicylates had but little affect on the temperature or course of the disease except that they relieved pain.

HOT AIR AND CALOMEL VAPORS IN THE TREATMENT OF CATARRHAL DEAFNESS AND OTHER MUCOUS MEMBRANE AND SYSTEMIC CONDITIONS.

By EDWARD J. BROWN, M.D.,

MINNEAPOLIS, MINN.

Following the publication of papers by me on the use of hot air and iodoform vapors (*Journal A. M. A.*, June 21, 1913), and calomel vapors in the treatment of constitutional and local conditions (*The Laryngoscope*, March, 1917), so many inquiries have come to me that a supplementary statement seems desirable.

I have found the hot air and calomel vapors incomparably superior to any other means of treatment of Eustachian and aural catarrh and other inflammations of the mucous membranes. In the treatment of catarrhal deafness a gentle current of the hot air is passed through the nares and the patient is directed to swallow every few seconds. In case the swelling of the Eustachian tubes is such as to prevent the sensation of air flowing into the ears upon swallowing, after a few minutes of the hot air, the nares should be closed and a sufficient current (minimum) permitted to pass to inflate the ears. The tubes are generally opened with slight if any extra pressure after one or two treatments. In some cases the catheter is used and the hot air applied directly to the tubes. The calomel vapors are then applied to the nasal chambers or directly through the catheter to the tubes and middle ears. My hot air apparatus is a section of half-inch gas pipe about a foot long placed vertically over my diagnostic gas burner, connected at one end with the compressed air service pipes and at the other with one-fourth-inch iron tubing and one-eighth-inch brass tubing bent as required to connect by rubber tubing with a glass nasal tube.

My calomel vaporizer is a three-inch section of half-inch gas pipe, over a Bunsen burner, connected at one end with the compressed air and at the other with a ten-inch section of quarter-inch pipe. The thread of both ends of the latter is filed off to make the ends slightly conical, one to fit tightly in the reducer and the other to serve as a nose piece. One having only electricity could have the tubing wound with a resistance coil, which would be as effective.

No current of air is required for ordinary use of the vaporizer, or a minimum at most. Two or three grains of calomel are sufficient for the usual local treatment, the dosage being regulated by the time spent in the inhalation, from one to fifteen minutes. A patient who may have an irritative cough from a one-minute treatment at first, will generally take from three to five minutes at the second or third treatment without complaint.

For constitutional treatment I have lately been using gray powder instead of calomel, as it is less irritating, allowing the patient to inhale the vapors from 15 to 30 grains for thirty minutes or more.

524 Syndicate Building.

Military Medicine.

ABDOMINAL DEFENSE IN WAR SURGERY.

WILLEMS (*Archives Médicales Belges*, May, 1917) refers to abdominal rigidity, so called wooden belly, a condition which the surgeon sees daily and which often furnishes indications for intervention. It does not, however, receive much special consideration in literature. We should examine for the presence of rigidity as a matter of routine after all lesions of the trunk. The patient lies flat on his back with head down and open mouth, thighs flexed on trunk at right angle, and knees separated. At first the hand makes slow, progressive pressure; and if this is quite possible to accomplish, then defence is absent. If the abdomen feels like a board as a result of muscular rigidity, then the abdomen is in a condition of extreme defence. Between these two extremes are other grades, as slight defence and partial defence. While extreme or major defence means peritoneal perforation, some of the intermediate degrees are less outspoken. When a hollow viscus ruptures and pours its contents into the peritoneal cavity extreme rigidity at once appears. It is, however, not necessary for a viscus to be opened for an effusion of blood into the cavity from a bullet wound will have the same effect; with this exception, that if the hemorrhage is not great the rigidity will be slight. Again, a retroperitoneal effusion will cause a kind of defence which will be mentioned later. Furthermore in wounds of the thorax with hemothorax there may be resistance. While major defence is explained readily by Stokes' law which governs the relationship of subjacent muscles to inflamed serosæ (for peritonitis is already beginning) this is not the mechanism of slight and partial defence, for here the peritoneum is irritated on its external surface, and not from within.

One may illustrate by examples. A man is shot in or near the abdomen. Within a short time the peritoneal reaction is intense and general. There is fluid in the cavity—is it blood or the contents of a viscus? Despite assertions to the contrary this question is not easily answered, for a free hemorrhage from a large vessel which floods the cavity will cause the wooden belly. In either type of accident intervention becomes urgently indicated, to ligate a vessel or suture a wound. In minor defence the smaller the resistance the less the diagnostic value and the significance for intervention. It is here that surgical second sight is called upon. A man is shot in the right hypochondrium, but shows no evidence of being seriously hurt. There is, however, a slight localized defence, which may reach down to the pelvis or across the median line. This man has been wounded in the liver and a certain quantity of blood has escaped into the pelvis. Should we open the belly? For what purpose? We know that the wound is not large. There is, of course, a possibility that bleeding will continue and the defence increase, and in such gravescent hemorrhage an exploratory intervention may be required. In every thoracic wound, as already stated, the abdomen should be examined, for the presence of resistance will throw some light on the character of the injury, but one must not hasten to do laparotomy in such cases. By the following day this resistance will probably have disappeared. In a wound of the loins with hematuria there is evidently a lesion of the kidney, although abdominal rigidity may coexist; but the indication for intervention will not proceed from the latter, but from the volume of blood which escapes by the urine. While the study of defence is illuminating one must not lay stress on it without comparison with the locality of symptoms.

Bearer Work on the Somme.—Sir Douglas Haig in a recent dispatch wrote that the losses entailed by the constant fighting threw a specially heavy strain on the medical services. Captain W. B. Jepson, referring to the subject in the *Practitioner* for September, 1917, says that in the Battle of the Somme all the orthodox methods of evacuating wounded were modified for the following reasons, among others: A continuous battle on an enormous scale was being fought over territory so heavily and methodically shelled that roads became impassable to vehicles; of shelter there was little or none, and water had to be carried up largely by hand. No buildings were spared by the enemy, so that advanced dressing stations were established in old trenches or dugouts, instead of the usual schools or churches. In spite of these difficulties, no blocking of the stream of casualties occurred within the knowledge of the writer.

The following notes, gathered as the result of some months' service in a field ambulance and a regiment may serve to describe how the exceptional conditions were met.

When a regimental medical officer became a casualty, his place was taken by an officer detailed from a field ambulance. Thus it occurred that Captain Jepson took over medical charge of a battalion, which was going backwards and forwards between the front line and rest. Under his charge were 16 regular stretcher bearers, eight reserves, a corporal, and his servant who acted as orderly. The stretcher bearers moved up to the trenches in rear of their companies, carrying, in place of rifles and ammunition, stretchers and haversacks of dressings. Each regular stretcher bearer wore on his left arm the S. B. or red cross brassard. The company stretcher bearers carried two stretchers, complete with slings, and a haversack. In the latter were carried first field dressings, shell dressings, compressed materials, large scissors, an iodine bottle with brush, and a reel of adhesive strapping. The regimental aid post had a surgical haversack containing chloroform, hypodermic syringe, morphine tablets, iodine bottle with brush, anchor pattern tourniquet, and instruments. In one handbag were kept the books of tallies, the tablet case, ammonia ampoules, a food warmer, "Tommies' cookers," and three electric torches. Reserve dressings were carried up in another handbag, with rations and medical comforts. A red cross directing flag completed the equipment of the aid post party, which consisted of the M. O., his corporal and servant, together with eight bearers under a non-commissioned officer. The bearers were temporarily attached to the battalion from the field ambulance. They carried their own rations, water, and haversack of dressings. This party moved up in rear of the regiment, clearing

any casualties which occurred before reaching the trenches.

The journey up was made before dawn or by night soon after dark. Any men falling out en route were seen at the end of the journey in the aid post, which was established in a dug out, shell hole, or by the roadside, sometimes with a neighboring medical officer; the advantage of this combination was that a rush of wounded could speedily be dealt with. In case of a casualty occurring, one surgeon could keep up the work of two until the relief arrived. The red cross directing flag was fixed in position on the nearest road, or at the mouth of the trench. The objection might be raised that this flag would draw fire, but it never did so in his experience. The aid post was usually near battalion headquarters, its position depending upon the available cover. The exact map reference was sent to headquarters, and an orderly was sent to each company to inform as to its whereabouts, and of the landmarks upon the way to it. The importance of stretcher bearers knowing their way, both by night and day, to the aid post cannot be emphasized too often. To this end, tape can be run out leading from battalion headquarters to the aid post if the way is very difficult to find.

At the bottom of the dugout a fire can be built, fuel being usually easy to find. Candles are put up in convenient places, and waterproof sheets and sandbags collected. In times of necessity, water, comforts, and waterproof sheets can be taken from the dead for the wounded.

When the battalion was ordered to attack trenches, the regimental bearers carried wounded from the new line to the starting off trench, whence casualties were removed to the aid post by the medical corps attachés. From here they were in the hands of bearers from the field ambulance post. At other times, the medical corps attachés carried as far as the bearer post, bringing back stretchers and slings always, and blankets, if available. From this post, extra dressings could be supplied. After an attack, all casualties should be cleared before dawn. In quiet times, a small party could often be sent out to search old trenches and shell holes. Great care should be given to this search. The party should turn over mackintosh sheets, stretchers, etc., for partly buried men, and should look for rifles reversed stuck in the edge of a shell hole. If a single bearer found a man, he should mark the spot carefully lest he should be unable to find the spot again. When dead of the regiment were discovered, their pay books were handed over to the adjutant, identity disks being left for the burial party.

The rescue of men lying out in No Man's Land should be effected with the minimum of exposure, for the loss of a trained stretcher bearer is keenly felt by his company. Abdominal wounds, head injuries and fractures were always passed on without delay. A man with fractured thigh was secured to the stretcher with bandages, sandbags being used to assist in the immobilization of the limb. Very slightly wounded men need not go down at once, but could assist their more seriously wounded comrades. Prisoners in charge of a guard cauld be made to carry down stretcher cases.

The stretcher bearers should be trained to mark their way across country, so that they do not lose themselves by night. They must beware lest they be put off the collection of their own wounded. Nothing disorganizes this so much as an order to collect a wounded man from a spot some distance away from the line held by the battalion. The collection of their own casualties is of the first importance. Dressings must be firmly applied, so that they do not slip down the limb. The use of adhesive strapping prevents this. They should be trained to economize in stretchers, that is, a slightly wounded man should not be carried down on a stretcher, when, with a helping hand, he could walk. Stretchers should be improvised from great coats, mackintosh sheets, etc. Messages from the front line telling of heavy casualties should be inquired into carefully before many bearers were sent up. Finally, constant evacuation was essential, so far as possible.

All the field ambulances of the corps were pooled and divided to form bearer camps, advanced dressing stations, a walking wounded camp, and a corps main dressing station. The motor ambulances became a circular service, running between the advanced dressing stations and the corps' main dressing station, and, lastly, the casualty clearing stations. By spreading the staff in this manner any abnormal pressure could always be adequately met. From the bearer camp, officers and other ranks relieved the bearer posts at regular intervals. At the advanced dressing stations walking cases entered one dugout, where dressings were renewed, if needed and tallies completed. To save unnecessary dressing some slight cases were labeled "No dressing required within twenty-four hours." They passed on to another dugout where tea and food were given. A record of all walking cases was preserved but stretcher cases were not recorded at the advanced dressing stations. For serious cases a larger dugout was set apart. They were carried in by one way and out to the waiting car by another. At night, the entrance to the dugout was marked by a lamp showing a red cross. Intercommunication by cycle orderly between advanced dressing stations insured a prompt supply of motor ambulances. At the walking wounded camp, antitetanic serum was given, together with food, and dressings again, if necessary. Walking cases were far more numerous than stretcher cases. All cases of shell shock were examined by a specialist at this camp. The corps' main dressing station was organized on a block system. Each block, consisting of four marquees, was independent of the others, being staffed by the tent division of a field ambulance. One block tended walking cases, another stretcher patients, and a third officer casualties. Officers and men were relieved regularly. Of the block the first marquee sheltered clerks, who filled in the medical cards; in the second, the wound was, perhaps, redressed; the third and fourth marquees served as mess tent and departure tent respectively.

The motor ambulances worked on a check system. Each loaded car en route for the main dressing station stopped at the motor transport headquarters, whence an empty car was sent off to replace it. It was found convenient to issue supplies of stretchers, blankets, dressings, and all medical

equipment from this headquarters. The ambulance drivers should know how to load up a stretcher case as well as how to drive a car. Others might be too busy to give assistance. The cars should be kept in good running order, but the maintenance of the full number of stretchers and blankets was of equal importance. If a car could transport eight sitting cases in times of pressure, it could certainly take four stretcher and four sitting cases. Of the latter, three sat down the center inside, and the fourth beside the driver outside. The weight was almost equivalent in both cases. Above all the chauffeurs should drive slowly when carrying serious cases, and know how to find their way by night.

Venereal Diseases in the Army.—Gaudy gives an extremely succinct account of venereal diseases in the European armies. The first point to be made is that warfare aggravates the course of these affections in addition to increasing their frequency. Among causal factors the youthfulness of the prostitute must first be mentioned, for youth connotes a recent, a contagious stage, and also ignorance of the nature of the diseases. Not only are there many very young girls engaged in prostitution, but many of the older ones are novices, and the results are the same. Absolute destitution is a factor, for some of these women, naturally virtuous, are menaced by starvation and exposure. Suppose that a woman in dire need solicits a soldier who has long been continent, and the outcome is not hard to predict. Statistics of value are very difficult to obtain, and some which the author cites are confessedly not reliable. This uncertainty holds good for attempts to show the amount of invalidism among soldiers with venereal diseases. There are numerous elements to be considered, such as neurasthenia provoked by chronic gonorrhea. Many soldiers with latent syphilis may seem in good health, but the disease may reawaken after the war.

In regard to preventive measures, Italy has been the most drastic country. A few brothels are tolerated for certain army units within the army zones. Civilians are forbidden access to these houses, which contain at most only 8 or 10 girls each. The latter have to accommodate an enormous number of men every day, but the small number of women makes rigid control possible. The men are made to use preventives of all kinds. With this plan is associated compulsory dispensary treatment by experts. All of these measures cause some diminution in the number of venereal infections—just how much is not stated. Germany and Japan have made use of similar plans.

In the Belgian army, lectures, talks and tracts are supplied, and a certain number of soldiers are favorably influenced thereby. But while the Belgians are not very religious or puritanical, harsh measures do not, for some reason, seem called for among Belgian soldiers; in fact, there is no widespread demand for them. There are few Belgian soldiers infected when at the front, and houses of tolerance in the war zone would only make matters much worse.—*Archives Médicales Belges*, June, 1917.

The Regimental Medical Officer.—The regimental medical officer shares the dangers common to the combatant officers and men, and stays with his battalion or brigade, as the case may be. His treatment can only be that of first aid, but he and his orderlies have saved innumerable lives, both by the rescue of wounded comrades from dangerous situations and by careful and rapid transport to the field ambulance sections in the support line.—*British Medical Journal.*

Conference of Presidents of Examining Boards.—A meeting of the officers and members of the various Examining Boards for the Medical Reserve Corps has been called at Camp Benjamin Harrison, Monday, October 8, 1917, at 11 A. M. This conference has the endorsement of the Surgeon General and already nearly one-half of the Boards have responded favoring the conference at that time. Important subjects will be brought before this conference and a large attendance is solicited. The call for the conference is signed by Dr. George M. Kreider, Springfield, Ill.

Mental Examination of Soldiers Begun.—The mental examination of every man in the Twenty-seventh Division has been begun with the examination of Company F of the Engineers. Every man will be examined as to his mental capacity, nervous temperament, peculiarities, etc. Men who give indication of being unable to stand the severest strain on the battlefield will be recommended for discharge. The work is to be conducted by Lieut. S. Leopold, who has just completed such an examination of the Pennsylvania National Guard.

Chloroform Chain Letter Banned.—A chain letter soliciting contributions to a fund for the purchase of chloroform has been sent out containing the following clause which the Committee on Public Information finds objectionable: "Owing to the scarcity of anesthetics, operations which cause indescribable pain have to be performed daily without their aid to mitigate suffering." The letter containing this clause has been submitted to representatives of both the French and British governments, who state positively that the statement upon which this appeal is based is absolutely without foundation, and object to solicitations for such a fund under false pretenses.

Bravery of American Surgeons Commended.—A recent cablegram to the Associated Press from the British Front in France and Belgium pays the highest tribute to the American surgeons in the advanced casualty clearing stations. It is reported that at Ypres-Menin several surgeons and assistants have been working steadily for several days while shells were breaking about them. Those who have witnessed the scene say they have never beheld a demonstration of greater coolness than has been shown by these men.

Airplane Ambulance a Success.—A recent cablegram from Paris describes the testing of an airplane fitted with two stretchers for carrying wounded soldiers. The airplane ambulance has been constructed by the French Army aeronautic service and during a twelve minute flight covered the equivalent of a fifteen mile journey. Dr. Chassaing of the Army Medical Service expresses the opinion that this method of transportation will be more suitable for the severely wounded than the ordinary ambulance owing to the fact that equilibrium of the airplane is so perfect that there is no unnecessary pain to the wounded passenger.

Women's Hospital Unit.—The French Govern-

ment has accepted the mobile hospital unit of the New York Infirmary for Women and Children for work in France. This unit was offered to the United States Government in July, but as women are not eligible to the United States Medical Reserve Corps could not be accepted. The unit will be composed of a hospital with 100 beds and small flying auxiliary units. It will work primarily among French women and children, but will also accept calls for the care of wounded soldiers. Dr. Caroline Finley is director of the unit and expects to go to France early in October to make preparations for the reception of the unit. Preparations here are in charge of an executive committee composed of Dr. Anna I. Von Sholly, Dr. Mary Lee Edward, and Dr. Alice Gregory. The expedition is backed by the National American Woman Suffrage Association.

Malicious German Rumor Disproved.—A recent cablegram from the British headquarters in France and Belgium states that German agencies have made special efforts to disseminate reports that serious differences have arisen between the British Army Medical Service and the American surgeons and physicians who have been working with the British forces in France. For the purpose of proving or disproving these reports a correspondent of the Associated Press has made a careful investigation of base hospitals and clearing stations in which American surgical staffs are working, as a result of which it can be confidently asserted that all these rumors are absolutely without foundation. On the contrary, it is stated that the utmost cordiality has and does exist between the British medical service and the Americans who are working with them. The reasons for circulating these reports are obvious. The object is to create among the Belgian and French civilians a contempt for America and Great Britain and consequently a hostility against these two nations.

Welfare Doctors for France.—A second Infant Welfare unit under the direction of Dr. Charles Ulysses Moore of Portland, Ore., has recently sailed to join the first unit which is under the direction of Dr. William Palmer Lucas of the University of California. The American Red Cross Commission announces that a third unit will shortly sail which will be under the direction of Dr. J. H. Mason Knox of Baltimore. With Dr. Knox's unit will go Dr. John S. Manning, Seattle; Dr. Florence Chapman Child, Philadelphia; Dr. Edmund J. Labbe, Portland, Ore.; Dr. Ethel Lyon Heard, Galveston; Dr. Helen H. Woodroffe, Ocean Park, Cal.; Dr. Dorothy Child, Philadelphia; Dr. O. H. Sellenings, Columbus, Ohio and Dr. Hugh Heaton of Melstone, Mont.

Cerebrospinal Meningitis at Camp Mills.—A death from cerebrospinal meningitis at Camp Mills, Mineola, N. Y., has lead to an investigation by Dr. Meader of the Surgeon General's Office. Cultures taken in the One Hundred and Sixty-seventh Infantry have shown quite a number of meningitis carriers. These have, of course, been isolated and a further spread of the disease is not anticipated.

Free Clinic for Speech Defects.—Among the plans being made for fitting wounded soldiers to occupy useful positions in civil life is that of establishing a free clinic for the treatment of speech defects. European experience has shown that the number of soldiers suffering from such defects, both as a result of wounds and in consequence of shell shock, is considerable. The institution has been incorporated as the New York Clinic for Speech Defects, with Dr. Herbert L. Wheeler, a member of the Medical Board of the Council on National Defense, as president. The clinic will be located at 143 East Thirty-seventh Street, New York, and will be open to the public early in October. It will be under the direction of Dr. James Sonnett Greene. The project is being financed by private philanthropy. Others actively identified with the conduct of the clinic are Dr. Abraham Jacobi, Thomas A. Edison, Dr. John MacKenty, and Dr. George M. Parker. It is stated that attention will also be given to teaching foreigners to speak English without a foreign accent, the accent being treated as a speech defect.

Sir Berkeley Moynihan, senior consulting surgeon to the Royal Army Medical Corps of the British army, and inspector of army hospitals in France, has been delegated by the British government to come to America to aid in the war preparations of the medical corps of the United States Army. He will take part in the war session of the Clinical Congress of Surgeons, to be held in Chicago the week of October 22, and will deliver the convocation address of the American College of Surgeons on October 26, bringing an official message of the Royal Army Medical Corps concerning the work of the surgeons on the battlefields and in the reconstruction hospitals of France and England. He will explain the needs to-day of the allied armies to save a maximum of the wounded, and will describe the notable advances in war surgery since the beginning of the war.

Clean Bill of Health for Spartanburg Camp.—Col. H. C. Fisher, Chief Sanitary Inspector of the Army, after a two-days' inspection of the training camp at Spartanburg, officially reports that the camp is in good sanitary condition, and that every precaution possible has been taken to protect the health of the troops quartered there.

Lieutenant George P. Howe of the U. S. Medical Officers' Reserve Corps was killed in action September 28, while on duty with the British forces in France. He was born in Lawrence in 1878, and was graduated from the Harvard Medical School in 1904. He was a member of the Massachusetts Medical Society and of the American Medical Association.

Medical Students to Continue Studies.—Announcement comes from Camp Upton that medical students sent by their local boards to the Seventy-seventh Division will be mustered out of the National Army, and will be permitted to continue their medical studies providing they enlist in the Medical Reserve Corps of the United States Army. Several medical students have already been mustered out.

Poets' Ambulance.—The American Poets' Committee which is providing ambulances for General Cadorna's army, instead of providing 50 ambulances, as originally announced, proposes to furnish 100. A unit of $2,000 provides one car. Twenty-eight cars have already been bought by cable, and 12 more are to be added with funds now in the hands of the committee. Reports from Italy state that ambulances are greatly needed on the Isonza front.

New York, October 6, 1917.

CHOLECYSTECTOMY VERSUS CHOLECYSTOSTOMY IN GALLSTONES.

DURING the past decade the development of gall-bladder surgery has been very rapid. Ten years ago cholecystostomy was almost universally employed in cases of cholelithiasis and of most other diseases of the gall-bladder that came to operation; whereas cholecystectomy is now considered by many of the most prominent surgeons to be the operation of choice. The technique of cholecystostomy itself has undergone one radical change during the past few years. Formerly the fundus of the gall-bladder was usually brought up to the wound and stitched to the peritoneal edges. It was found, however, that this practice frequently led to late postoperative complications, due to adhesions and dragging on the attached gall-bladder; hence, unless unusually long drainage is desired, it has become the usual practice to anchor the drainage tube in the gall-bladder by catgut suture, invaginate this suture line into the gall-bladder by one or more rows of purse-string sutures, allow the gall-bladder to assume its natural position, and close the abdominal incision to the point of emergence of the drain. When long-continued drainage is desired the old method of attaching the fundus of the gall-bladder to the peritoneum or rectus sheath is still employed.

Cholecystectomy, however, is coming more and more into vogue; for it has been shown that while, in cases of cholelithiasis, removal of the gallstones and temporary drainage may result in a permanent cure, relapses are not at all infrequent since a diseased, infected gall-bladder is left behind. Then, too, it has gradually become recognized that cholecystitis is the disease and that gallstones are merely secondary; hence in a large percentage of the cases the gall-bladder itself must be removed if permanent cure is to be obtained.

We do not wish to be understood, however, as recommending cholecystectomy in all cases, nor is this the suggestion of even the radical exponents of that operation. There are certain cases in which prolonged drainage is essential, notably in those with marked concomitant pancreatitis; and in these drainage of the gall-bladder is vastly superior to cholecystectomy with drainage of the common duct. Then again, the amount of experience which the operator has had in gall-bladder surgery must be taken into account; for while simple drainage of the gall-bladder is usually a comparatively easy operation, cholecystectomy is often extremely difficult. Even in the ordinary cases of cholelithiasis, and with men of approximately equal skill, opinion is divided as to whether cholecystectomy or cholecystostomy should be the method of choice; while in the face of complications of one sort or another the question is still more undecided.

To get, if possible, a crystallization of opinion on this matter Guthrie sent out a questionnaire to forty-five experienced abdominal surgeons; and recently (*Interstate Medical Journal*, August, 1917) he has again taken up the subject under the title: "Cholecystectomy, a better but a more dangerous operation than cholecystostomy." The questions submitted to the forty-five representative surgeons were as follows: (1) What percentage of cases of cholecystostomy have had a recurrence of trouble following operation? (2) Are you performing cholecystectomy more frequently than in the past? (3 Have the results been better than when simple drainage was used? (4) In what cases do you consider cholecystectomy the operation of choice? (5) What are the contraindications to its employment? (6) As a rule how do you treat empyema of the gall-bladder? (7) How does the mortality of cholecystectomy compare with that of cholecystostomy in your work?

The average percentage of recurrences after cholecystostomy reported by 29 men was 9.5 per cent. and varied in individual cases from 1 to 33 1/3 per cent. Thirty-six of the 45 surgeons reported that they were doing cholecystectomy more frequently than formerly. To the question whether the results were better with cholecystectomy than with simple drainage 36 answered "yes," 7 "no," and 2 did not answer. Answers to the question, "In what cases do you consider cholecystectomy the operation of choice?" are given at considerable length and can hardly be satisfactorily abstracted. However, Guthrie says: "The chief indications for removal given by the majority are any disease of the wall of the gall-bladder itself or damage to the cystic duct. . . . Eighty per cent. advise removal when any disease of the gall-bladder wall, with or without stones, is found." In the compilation of contraindications for cholecystectomy Guthrie finds the chief ones to be: Inexperience of the operator; inexperience of the anesthetist; desperate condition of the patient, which will not permit prolonged operation; extreme obesity, where good exposure cannot be obtained; perihepatic adhesions which make it impossible to draw the liver well down and rotate it outward through the wound; pancreatic disease and acute empyema. Thirty-three out of 44 men who replied to the sixth question favored treating acute empyema of the gall-bladder by drainage. Some of the others advise primary drainage, followed later by cholecystectomy; while six favor primary cholecystectomy. In

answering the question as to the comparative mortality of cholecystectomy and cholecystostomy, two men stated that the difference was not known; four had a lower mortality for cholecystectomy than for cholecystostomy; 18 reported the mortality the same, and 21 had a higher mortality for cholecystectomy than for cholecystostomy, the difference ranging from 0.5 to 3 per cent.

Guthrie's summary and conclusions are as follows: "Reports show that recurrences happen in 9.5 per cent. of cases that have have had cholecystostomies performed. The recurrence of trouble following cholecystectomy is certainly small; the exact percentage is not known. Cholecystectomy is employed much more frequently than in the past and is a better operation, but it is attended with many more operative difficulties and dangers than simple drainage. The gall-bladder should be removed when its wall is diseased or the patency of the cystic duct is in question, provided the patient's condition will permit it. The contraindications for the operation are critical states of the patient, acute empyema, infection of the ducts, and pancreatitis, where drainage is desired. It is safer to treat acute empyema of the gall-bladder with simple drainage, and only proper to explain to the patient that a second operation may be necessary. Two safe operations are much better than one dangerous one, and in case of doubt simple drainage should be employed, especially by those inexperienced in gall-bladder surgery."

This certainly seems a fair statement of the case. The advantages of cholecystectomy over cholecystostomy as regards permanent cure are quite evident, and professional opinion seems to be inclining to the view that as soon as the operator acquires adequate experience and technical skill cholecystectomy should be the operation of choice in a large percentage of gall-bladder cases.

THE ETIOLOGY OF GOUT.

SINCE the discovery by Scheele in 1776 of uric acid in urine this substance has always been associated more or less with gout and with the so-called gouty diathesis. But while the association between the two is still held there is now a great deal of doubt as to the exact causal relation. Indeed, there is little more than conjecture on the pathological aspect of uric acid in gout. The pathological romances woven around this substance are not borne out by experiment, yet the purin bases, of which class uric acid is a derivative, are probably at the bottom, chemically at least, of the gouty condition. Purin itself has not been discovered as such, but in the body it forms the bases for the so-called purin bodies—hypoxanthin, xanthin, adenin, guanin, and uric acid. The purin base is ingested with a number of foods, particularly those rich in nucleoproteins, and the treatment of gout even now includes the prohibition of such foods. But Magnus-Levy, Voigt, and others demonstrated that even the administration of foods very rich in nucleoproteins, such as thymus gland, liver, and pancreas do not increase the uric acid excretion, at least no more in gouty persons than in normal ones. Spitzer believed that there is present in the organism, probably in the liver, pancreas, and spleen an enzyme which oxidizes and converts the purin bases into the component derivatives.

There is much doubt whether uric acid is present in any considerable quantity in the blood. The amount present itself does not account for the deposit of urates. In leucemia, for example, there is a great deal of uric acid yet no deposit of urates. The blood is always able to dissolve more uric acid than it contains. Nevertheless, an accumulation of uric acid in the blood is still believed to be a constant accompaniment, if not the actual cause, of gout. On this theory an acute attack of gout is the unsuccessful attempt of the organism to rid itself of this accumulation. Bearing upon this view there is a suppression of uric acid elimination before an attack and an increase during and immediately thereafter. Whatever accumulation of uric acid there is in the blood with the lessened excretion, it is due in all probability to some disturbance of renal function brought on in some manner by the presence of uric acid in an abnormal chemical combination. The same condition has been credited to an unusual behavior of the uric acid in the metabolism of the nuclei of the cells that hold and keep in solution the purin bodies. Except where there is palpable renal disturbance in gout the ingestion of increased amounts of nucleoproteins is held not to affect the amount of uric acid. Primarily it must be an organic disturbance which causes the metabolic changes and biochemical peculiarities of this disease.

Minkowski suggests that the whole matter of purin action in gout is the result of an individual or hereditary intolerance for purin bodies; and that this tolerance or intolerance is brought about through the presence of the ferments especially purposed for the oxidation of these bodies. The tolerance or intolerance is constitutional in a great many individuals. Gout is more common than is usually supposed. Most cases of so-called chronic rheumatism are gouty. Indeed, by many it is maintained that there is no cause for believing there is any such disease as chronic rheumatism, this affection being either gout or arthritis deformans in varying degrees of mildness. Probably also traumatic, toxic, and infectious elements play an important part in provoking the organic and metabolic disturbances that set up an attack. The tissue changes in and around the gouty deposits are purely local, the result of chemical, vasomotor, and mechanical action of the deposits.

In the treatment of gout the hypothesis that intolerance of the organism to purin is marked is still adhered to, and foods rich in these bodies are strictly interdicted. Alcohol in general is prohibited because it is believed to have an adverse influence upon the oxidizing power of the ferments acting upon the purin bodies. In the case of beer the interdiction is based upon the fact that the

brewer's yeast which enters into the manufacture of this product is very rich in nucleoproteins. It is not at all improbable that all the present theories on this disease will become obsolete on the advent of the newer developments in biochemistry.

THE ELECTRICAL STERILIZATION OF MILK.

Boiling and even pasteurizing milk is believed to destroy to a greater or lesser extent some of its nutritive properties, and although pasteurization has been of almost inestimable value in saving the lives of young children it is not an absolutely perfect method. Therefore any means whereby milk can be freed of disease-bearing bacteria, while, at the same time, its chemical constitution is unaltered, is worthy of consideration.

According to Dr. Joseph Priestley, writing in the *Practitioner* for September, 1917, an interesting series of investigations has been carried out recently in Liverpool with regard to the value of the use of electricity as a milk sterilizer as compared with the more usual methods of heating. The results and conclusions to be drawn from the investigations into this method are best given in the words of Prof. J. M. Beattie, the investigator, in his report, published in the *British Journal of State Medicine*, as follows: (1) The electrical method of treating milk will destroy the disease-bearing bacteria present in it; (2) the usual milk souring bacteria are either completely destroyed, or, if some members of this class are left, they may be neglected so far as the keeping properties of the milk are concerned for ordinary household use; (3) the milk is not sterilized in the strictest sense of the word, but there is a reduction in the total number of bacteria by 99.9 per cent.; (4) the milk will keep perfectly sweet for, at least, three or four days after treatment; (5) the chemical constitution of the milk is, so far as can be ascertained by chemical analysis, unimpaired and the taste is not in any way altered; (6) the milk is not only rendered non-pathogenic as regards ordinary bacteria, but, in cases in which the control supply was tuberculous, the electrically treated milk is free from tubercle bacilli; (7) the milk, after treatment, is perfectly satisfactory as a food for infants.

If the results of the above investigations are confirmed it would seem that electrically treated milk has some points of superiority over pasteurized or boiled milk.

Rats.

For many reasons, economic and hygienic, even apart from their pernicious agency in the spread of bubonic plague, the extermination or reduction in numbers of rats on shipboard is a matter of great importance. The measures most commonly resorted to as giving the best results are trapping and fumigation. Trapping is effectual, but to be of service, according to Drs. Creel and Simpson, writing in the Public Health Reports of September 7, 1917, must be done by skilled men specially selected for their efficiency. Fumigation of vessels is another means by which the rat population is kept within bounds. There is a difference of opinion as to which are the best fumigating agents for this purpose, whether sulphur dioxide or cyanide gas. According to the report of Creel and Simpson, based on actual tests made with these two gases, cyanide would appear to be more effective in the fumigation of loaded holds, but in empty vessels there is no material difference in the results obtained. One disadvantage of sulphur dioxide is that on account of its odor it may give warning to the cunning rodents and enable them to secure greater protection. On the other hand, cyanide, with less obtrusively unpleasant smell, and without the physically irritating properties of sulphur dioxide, will often kill the animal before it can find a safe haven. The strength of the gas and the length of the exposure appear to depend largely, if not entirely, upon the lading of the vessel. If a hold is filled with cargo, a greater strength of gas and a more prolonged duration of exposure are required. No method of fumigation as yet tested has shown absolutely perfect results, nor can any such method be expected to bring about so ideal an end, but cyanide gas, employed with intelligence and with regard to the safety of humans, appears to be the most effective agent for ridding vessels of the menace of the rodent.

Return of Menstruation at the Age of Ninety-two.

Many so-called curiosities of medicine as told in past years become in part intelligible to-day because of our acquisitions in the new science of endocrinology. But owing to the imperfect character of many of these reports conjecture must take the place of demonstration. In the *Revista de Medicina y Cirugia* of August 25, De Jong narrates a case of the return of the menses in a very old negress, who in other respects did not differ from others of her race and time of life. According to the testimony of her relatives she had first menstruated at 10 years and had borne her first child when 15. She had had eight children by the time she was 29. At this period her menses ceased for several years. At 34 they reappeared and persisted for an indefinite period—somewhere between 40 and 43, during which interval she had a miscarriage. Up to the age of 60 she retained her habitual vigor, but soon afterward began to show evidences of senile involution. At 92 she experienced swelling and tenderness of the breasts with inflammation of the vulva and an acid discharge from the vagina. She then developed pain in the ovaries and an abundant metrorrhagia. During an observation period of five months she menstruated quite regularly, the discharge lasting five days. The menstrual period was, moreover, attended by a sexual reaction toward the men of her acquaintance, although in the intermenstrual cycle she was wholly indifferent.

Attempted Suicide with Adrenalin.

At a recent session of the Société médicale des hôpitaux (*La Presse Médicale*, August 9), Grasset related the case of a man of 26, in advanced con-

sumption, who drank 35 c.c. of a 1 to 1000 solution of adrenalin in two successive doses with suicidal intent. Although the man seemed to be in no danger of his life he was treated with emetics, amyl nitrite, venesection, hypodermics of camphor and caffeine, and an infusion of 250 c.c. of artificial serum. In two days he was free from symptoms. The tolerance shown in this case suggested that in subjects with supple arteries the ordinary dose of adrenalin could properly be increased. As a typical case the observation is a failure, however, because the victim swallowed one or more other substances of unknown nature which may or may not have excited a toxic action. Professor Sergent, in discussion, explained why the use of adrenalin solution by the mouth is relatively contraindicated. In doses too low to cause vasoconstriction it is, he states, quite inert; and to produce vasoconstriction the hypodermic route is much the best. If given per os the small, fractional, repeated dose is superior to the massive dose for producing vasoconstriction; besides, the latter is also able to set up certain undesirable congestions.

News of the Week.

France Puts Ban on Drunkenness.—The Chamber of Deputies has passed a bill forbidding drunkenness in public places. The bill provides that any one found intoxicated in the streets, in saloons, or public places shall be fined from one to five francs for the first offense and imprisonment for three days as the maximum penalty for the second offense. The penalty for the third offense within a year from the second is a fine of from sixteen to three hundred francs, in addition to imprisonment from six days to a month. Those incurring four convictions within three years may be deprived of civil rights and of parental rights over children.

Anthrax in California.—An epidemic of anthrax in Yolo County, California, has reached an alarming stage, being the worst in the history of the country. The disease has spread to the adjoining county. The State veterinarian, according to press reports, makes the statement that he feels confident that the germs are being spread by agents of the enemies of the United States. Evidence has recently been brought to light showing that German agents have been guilty of spreading anthrax germs among cattle in Roumania and Bulgaria.

Cornerstone of Randall's Island Building Laid.—The cornerstone of the first of eleven new buildings now in the process of construction on Randall's Island was laid on September 24. This building is to be known as the Institution for Feeble Minded Children. Mayor Mitchel was the principal speaker. The other speakers were Commissioner of Charities John A. Kingsbury and Dr. Walter F. Fernald.

Educational Agencies of New York State Department of Health.—The September Bulletin, issued by the State Department of Health, gives a full description of the educational agencies of the Department, and a summary of information regarding the exhibits, slides, films, charts, models, and other educational equipment of the department for the convenience of public health workers, organizations, and communities contemplating public health work. These exhibits cover practically every field of public health work even including a number of motion picture scenarios. The Department is always ready to loan these exhibits and invites correspondence with reference to special problems or subjects, or more detailed advice as to methods of conducting a health campaign than is embodied in the Bulletin.

Hospital for China.—The cornerstone of the $2,000,000 hospital and medical college which the Rockefeller Foundation is establishing in Pekin, China, was laid on September 24 by Fan Yuen-lien, Minister of Education. Dr. Frank Billings of Chicago, who is returning from his work with the Red Cross Mission to Russia, made the principal address.

New Course in Health Study.—A Department of Vital Economics has been established at the University of Rochester in connection with the Department of Household Economics of the Mechanics Institute. The course is arranged to give instruction in more rational physical living and to prepare young men and women for positions in public health offices. Dr. John R. Murlin, for eight years professor of physiology in the Medical School of Cornell University, has been appointed director of the department. The organization of this department has been made possible by a bequest of $800,000 under the will of Lewis P. Ross, the income of which is to be used "to the end that human life may be prolonged with increased health and happiness."

New York "Springs" a Source of Typhoid Fever.—A small outbreak of typhoid fever in the Borough of the Bronx has led to the interesting discovery that infection was probably conveyed by the drinking of water from an infected spring fed by the drainage from fertilized fields in the vicinity. Further investigation has made it evident that the water of other springs in that part of the city is unfit for drinking purposes. The Department of Health warns against the drinking of water from any springs located within the city limits.

Universities Open.—Columbia University and New York University opened on September 26. The main theme of the various opening addresses was the opportunities for national service. It was forcibly impressed that while every man was called to the service of his country, university men were called with a double insistence.

Civil Service Examinations.—The Civil Service Commission of the State of New York announces the following examinations for November 3, 1917: An examination for Assistant Bacteriologist, State Department of Health, open to men and women between the ages of 21 and 35 years. The salaries range from $1200 to $1800 a year. Candidates must be graduates of a college maintaining a standard satisfactory to the Civil Service Commission, must have a thorough knowledge of the principles of bacteriology and considerable laboratory experience. Non-residents and citizens of other countries, except those at war with the United States, are eligible. An examination is also announced for the position of assistant physician in the State hospitals and for other positions of a similar nature in various State and County institutions. The salaries in the State hospitals are $1200 the first year with an annual increase of $100 each year to $1600, with maintenance. The examination is open to men and women, licensed practitioners of New York State, with one year's experience on the residential medical

staff of a general hospital. Applications must be filed not later than October 24, 1917.

The Washington County Medical Society at its annual meeting held in Montpelier, Vt., September 12, elected the following officers: *President*, Dr. C. H. Burr of Montpelier; *Vice-President*, Dr. M. L. Chandler of Montpelier; *Secretary and Treasurer*, Dr. H. A. Whitney of Northfield.

The Utah State Medical Association at its annual meeting held in Salt Lake City, September 12 and 13, elected the following officers: *President*, Dr. Fred Stauffer of Salt Lake City; *First Vice-President*, Dr. A. J. Stewart, Provo; *Second Vice-President*, Dr. Edward I. Rich, Ogden; *Third Vice-President*, Dr. Ernest Van Cott, Salt Lake City; *Secretary*, Dr. W. Brown Ewing, Salt Lake City; *Treasurer*, Dr. F. A. Goeltz, Salt Lake City.

Obituary Notes.—Dr. AUGUST GEORGE HORSTMAN died at his home in Brooklyn, N. Y., on September 26, aged 40 years. He was a graduate of the Cornell Medical School, in 1906, and was formerly connected with the staffs of the German and Jewish hospitals of Brooklyn.

Dr. JAMES H. WILLIFORD, a graduate of the Medical College of Ohio, in 1874, died of heart disease at his home in Dawson, Ga., September 11.

Dr. THOMAS J. SHREVES, a graduate of Rush Medical College in 1857, and for sixty years an active practitioner of medicine, died at his home in Des Moines, Ia., September 7, aged 82 years.

Dr. L. M. ANDREWS, a Confederate war veteran, and for many years a practitioner of Greene County, Ga., died September 15, aged 82 years.

Dr. CHARLES GENNERICH, a graduate of the New York Homeopathic Medical College, in 1896, and a member of the American Institute of Homeopathy, died at his home in New York, on September 14.

Dr. JAMES C. BYRNES, retired, died at the home of his brother-in-law, Dr. R. B. MacGruder, in Brooklyn, N. Y., September 15, aged 66 years. Dr. Byrnes was in active service for forty-three years. He was an assistant surgeon during the Indian wars and served on the *Cincinnati* during the Spanish-American War. Later he was fleet surgeon of the Pacific squadron. In 1909 he was appoinaed to command the Naval Hospital at Newport, and in 1910 became director of the naval hospital in Brooklyn, retiring in 1913. Dr. Byrnes was a graduate of the Georgetown, Md., School of Medicine, in 1870.

Dr. AUGUSTINE B. LIBBY, a graduate of the Baltimore University School of Medicine, in 1894, died at his home in Smyrna Mills, Me., on September 6, after a long illness, at the age of 60 years.

Dr. WILLIAM ANDREW BINDEWALD, one of the oldest physicians of Louisville, Ky., died in that city on September 15, aged 76 years. He was a graduate of the University of Louisville Medical Department, in 1871.

Dr. CHARLES W. NUTTING, a graduate of the Atlanta, Georgia, Medical School, in 1876, died at his home in Etna, Cal., about September 18, aged 65 years.

Dr. JOHN SWOPE MATHIAS, a graduate of the University of Maryland School of Medicine, in 1879, formerly of Westminster, Md., died at the home of his son in Kansas City, Mo., on September 17, aged 62 years.

OUR LONDON LETTER.

(From Our Regular Correspondent.)

AEROPLANES ARRIVING—HOSPITALS ATTACKED—VARIOUS EFFECTS OF THE EXPLOSIONS.

LONDON, September 8, 1917.

ENEMY aeroplanes in considerable numbers have come across the channel. Some traveled singly, others in groups of two or three, so that it is difficult to estimate their total number, but it is thought twenty or more machines took part in a raid. Some forty bombs were dropped in this district and others at various places on the coast. The material damage was less than might have been expected. The bombs dropped were not more than about 15 inches long and about as thick as the top of a half-pint glass. Three distinct attacks extending altogether over two hours were made; after the third, which kept droning in the neighborhood above a quarter of an hour, all was quiet for a time; then thousands of people poured into the raided district as soon as the news got abroad and passed in a ceaseless procession along the streets where the raiders had dropped their bombs; broken windows and shattered walls testified to their activity. A hospital, too—the Huns' favorite prey—narrowly escaped demolition. A nurse, describing the raid, said she heard a whizzing sound followed by a loud explosion and felt a choking sensation; she thought a bomb had fallen on the hospital, but that was not the case; the only part of the building sustaining damage was the front door and some windows which were blown in. Yet so fierce was the explosion that a block of wood paving from the road was hurled right over the building. Another nurse, who at the moment was in a distant part of the hospital, was whirled round by the force and flung against an opposite wall. Three American doctors who were present rendered first aid where needed. A canary in a gilt cage meanwhile sang merrily amid the débris.

OUR LETTER FROM PARIS.

(From Our Regular Correspondent.)

THE REDUCED BIRTHRATE IN FRANCE—CRIMINAL ABORTION—CARE OF INFANTS—FETAL DEATHS FROM SYPHILIS.

PARIS, Sept. 3, 1917.

AT the latest bimonthly meeting of the Academy of Medicine, Dr. Pinard, the veteran professor of obstetrics, presented the second report of the Commission appointed by the Academy to study the question of abortion in France and particularly how to encourage the birth of children among the women who seek to rid themselves of their embarrassment when so unfortunate as to become enciente.

The medical situation in France in relation to this question is strangely curious. Any doctor who is found party, directly or indirectly, to abortion is relentlessly prosecuted, as he should be, but there exists a legalized body of women, as a sort of department of the practice of medicine, called sage-femmes (midwives), handed down from the practice of the Middle Ages, who specialize in the care and delivery of women in childbirth, particularly those of the poorer classes who cannot afford to em-

ploy a regular physician. These women in many instances have one or more bedrooms to let to women expecting to be confined and can receive them as boarding patients. Many of these sage-femmes make a specialty of taking in women and performing an abortion for them and the fact that they do this is an open secret. Many of these patients, as soon as they have their miscarriage, are put into a cab and sent to the hospital for care through their convalescence, and one part of Dr. Pinard's report deals with this feature.

The Commission was asked to study the causes of the depopulation and make recommendations for combating it. Their first report gave rise to a discussion which showed wide divergence in the views of the members of the Academy and especially among the members of the Commission with the result that they were requested to consider further the questions brought up and make a new report.

The second report renewed the demand made in the first one that the women admitted to the hospitals suffering from the effects of miscarriage be reported to the authorities for an inquisition as to the cause, and those connected with it. It also insists upon the prompt and proper protection, before and after birth, of the infants born at term, relieving the mothers wholly of their care, if requested, and furnishing to each mother who elects to charge herself with the care of the child a daily allowance by the State of sufficient to sustain or bring it up; this allowance to be duplicated for each child born to her.

The question of the reduced birth rate in France has been constantly before the public since the wars of Napoleon the First, and is as far from solution to-day as ever. It is almost as difficult and delicate a question to solve as that of regulating the venereal diseases; no matter what is proposed, at once an army of objectors come forward with as many varieties of objections. No sooner does the recommendation of this Commission become public than Dr. Rochard of l'Hôpital St. Louis appears in print with a long letter protesting that to carry into effect the report of the Commission is to invade the sacred province of professional secrecy and that the effect of such action by the hospitals would be to prevent the women from seeking medical aid, leaving them to die from infection or neglect, which would serve to increase rather than decrease the depopulation.

I have heard it stated that there are in Paris five abortions to every birth at term. In my hospital service I have more than once been told by a young woman that she would willingly bear her child if she could be protected from disgrace and relieved of the burden of care and support of the child. Any one who can propose an acceptable solution to this complex question will render an inestimable service to France.

Professors Girauld and Tissier reported their statistical studies showing that not only does syphilis cause the frequent death of the fetus *in utero* but that it greatly diminishes the birth of masculine children.

Dr. Vaumezon, at the same meeting of the Academy, presented a paper treating of the paratyphoid and colon bacilli as found among the troops at the front, stating that the first named shows the greatest resistance to all of the agents employed against pathogenic germs in general.

146 Avenue des Champs Elysées.

"RESEARCH WORK INTERRUPTED."

To the Editor of the Medical Record:

Sir:—In his explanation of my dismissal, in the Medical Record of September 22, the Commissioner of Health gives a new version which is not only at variance with the facts but also contradicts his own statement in the *New York Times* of September 16, which reads, "The reason for his discharge was in connection with a report which he prepared on the effect of whooping-cough vaccine." Dr. Emerson apparently feels that such a statement in the Medical Record, whose readers are not laymen, but physicians well acquainted with my work on pertussis, would not hold and he therefore makes the vague accusation of "insubordination and disobedience." Furthermore, he seeks to hide behind the Board of Promotions. He endeavors to give the impression that the Board wanted me dismissed and that he had simply carried out its request. To those unacquainted with the organization of the Department this might appear plausible, but the well-informed know that the Board of Promotions is merely a "rubber-stamp," composed of the Commissioner's assistants who do as they are instructed.

I challenge Dr. Emerson to publish the specific charges of "disobedience and insubordination," as I can easily prove with witnesses and documents to any impartial committee that they are absolutely false. I repeat that the Commissioner ordered me to stop my research work on alcohol or resign and that upon my refusal to do either, he determined to dismiss me. It is not true that Dr. Emerson wanted me to control, verify, or controvert what had been written on alcohol. What he wanted me to do was to bring in a report sustaining his public lectures on prohibition. He had not enough patience to wait for a complete report and kept on pestering me for a preliminary résumé, which I finally submitted to Dr. Williams, who was in charge of the Laboratory during Dr. Park's absence. The latter, therefore, could not have passed upon the scientific value of my work, and Dr. Emerson constituted himself its only judge. This he admits in his statement to the press in the following words (italics mine): "I looked it over *myself*, and from *my* knowledge of Physiology *I* saw that it was a bad piece of work."

As to the "freedom and facilities" given me in carrying out this research work, your readers may form the right conception from the fact that I was allowed only one-third of the time of a single assistant, that the munificent sum of $9.00 was allotted for the purchase of alcoholic liquors, and that I had to devote the largest part of my time to routine work in the meningitis department.

Paul Luttinger, M. D.

Inversion of the Uterus in Holland During the Past Twenty Years.—De Lint tabulates an analysis of twenty-nine cases. But six ended fatally, and save for a decease from cancer one year after the accident there is no record of further death.—*Nederlandsch Tijdschrift voor Geneeskunde.*

Progress of Medical Science.

Boston Medical and Surgical Journal.

1. Hemorrhage: Accidental, Inevitable, Postpartum. Robert L. De Normandie.
2. Chronic Valvular Heart Disease in Pregnancy and Labor. Foster S. Kellogg.
3. The Technic of Abdominal Cesarean Section, and a Report of Sixty Cases. Robert C. Cochrane.
4. Bleeding in Pregnancy. Raymond S. Titus.
5. The Management of Labor. C. P. Twitchell.

I. Hemorrhage: Accidental, Inevitable, Postpartum.—Robert L. De Normandie says that until the laity is educated to the fact that bleeding during pregnancy is abnormal and calls for immediate and careful diagnosis as to its cause, until all physicians take this definite stand and act accordingly, we shall have a large mortality, some of which is nothing short of criminal and some of which, however, will always be unavoidable. There are two types of accidental hemorrhage characterized by the presence or absence of external bleeding. The diagnosis of accidental hemorrhage may be made on sudden pain, alteration in the feel and size of the uterus, pain on palpation, pallor, prostration, normal lower uterine segment. The treatment without a question is to empty the uterus with all possible speed with due regard to the patient's soft parts. The method to be used for this purpose depends upon a number of variable factors. In marked contrast to the onset of an accidental hemorrhage a placenta previa announces itself by bleeding without pain, without apparent cause, not infrequently while the patient is sitting or lying down. This one sign, in a woman pregnant more than three months, of bleeding without pain or cause should make any thinking physician suspect even before he saw the patient that a placenta previa was present. Palpation of the uterus with this condition shows it to present the normal uterine feel either of a uterus in labor or not in labor. The presenting part not infrequently is quite high. Bleeding without accompanying pain and the presence of a boggy mass in the lower uterine segment are the necessary points upon which a diagnosis is based. In a suspected previa one should never attempt a cervical examination until preparations have been made to do more if necessary. Though the need for immediate delivery in this condition is not so imperative many times as in accidental hemorrhage, no unnecessary delay is permissible. The condition of the cervix is the underlying point determining what treatment had best be given the individual problem, whether the gauze pack the Voorhees bag, Braxton Hicks version *accouchement forcé* (not a ruthless divulsion, but a gentle manual dilatation) or a cesarean section. This latter should, however, not be undertaken unless the mother is in good condition, her soft parts rigid, and the baby in good condition. The third type of hemorrhage considered—postpartum—is usually caused by some error of the physician, frequently by his having hurried the third stage of labor. Another cause is that many physicians fail to inspect the membranes and placenta. If the membranes are lacking or only partly lacking the writer never goes after them unless the uterus shows signs of inefficient retraction and therefore a tendency to bleed. If the placenta is not complete, especially if a placenta succenturiata is diagnosed, then the interior of the uterus should be explored under the strictest aseptic precautions. Never fail on any obstetric case to be prepared to meet a postpartum hemorrhage. The writer says that he seldom used an intrauterine douche to stop a hemorrhage, but gives preference to pituitrin, ergot, and ice to the fundus. If these are not effective the gauze packing is indicated.

2. Chronic Valvular Heart Disease in Pregnancy and Labor.—Foster S. Kellogg has made a study of the records of 30,000 cases as follows: 7,200 pregnant women observed in the Prenatal Clinic at the Boston Lying-in Hospital, 22,055 pregnant women entering the Boston Lying-in Hospital for delivery or care in pregnancy from January, 1913, to June, 1915. He finds that one-half of 1 per cent. of pregnant women have chronic endocarditis. Fifteen to 20 per cent. show some decompensation under prenatal care; half of these show a first degree compensation and one-half a second degree decompensation. Cases with stenosis of the mitral valve, with or without insufficiency, are far more likely to decompensate in pregnancy than cases with simple insufficiency. The maternal mortality of chronic valvular disease in pregnancy is 2 per cent. The maternal mortality of cases showing second degree decompensation requiring induction, and second degree decompensation in labor is 45 per cent. Mitral stenosis is almost always present in fatal cases. The fetal mortality runs from 10 per cent. in a series including all cases to 40 per cent. in cases with second degree decompensation. Chronic valvular heart disease complicating pregnancy is, in view of these figures, potentially a very serious condition for mother and child. One-half or these cases not under good previous care for their heart condition, which show decompensation, will recover sufficiently under medical treatment, rest, and proper regulation of their lives, so that they do not again decompensate, and so that they will stand any appropriate method of delivery at term. Normal delivery and *accouchement forcé* have no place in the treatment of chronic valvular heart cases in pregnancy and labor. It is not justifiable to attempt to carry a woman who is decompensated to term for the sake of her baby unless she reacts favorable to treatment almost immediately. "Cardio pregnancy literature," as a whole, is inadequate because no classification is used to determine the factors in the cases under discussion. Some classification is deemed necessary which will visualize, at least, the period of pregnancy, the degree of decompensation, and the character of the cervix, and whether or not the patient is in labor. The author presents such a classification and his beliefs as to the proper obstetrical handling of these cases.

1. The Question of Blood Pressure.—Robert Franklin Ives presents a résumé of recent studies in reference to the significance of variations in blood pressure from which he draws the following conclusions to be accepted as suggestive and not as dogmatic: (1) The pulse pressure is always large in aortic insufficiency. In fact it is the largest seen in any disease. (2) In chronic nephritis the pulse pressure is always high in the stage of compensation, and in decompensation must be restored to maintain the circulatory balance. (3) In pulmonary tuberculosis the pulse pressure is low in advanced cases. (4) Hypotension with decreased pulse pressure is a bad omen in acute myocardial degeneration, a subsequent rise restoring the prognosis for immediate recovery. (5) When the systolic pressure is normal and the diastolic low, increased pulse pressure means peripheral relaxation or splanchnic dilatation. (6) When the systolic pressure is high increased pulse pressure is normal if the ratio is maintained. When the systolic pressure is very high and the diastolic unusually low, giving a very large pulse pressure, the condition of complete heart block is suggested. (7) With low systolic pressure, increased pulse pressure occurs in one condition only, and that is aortic insufficiency. (8) With normal systolic pressure a gradually decreasing pulse pressure means the gradual onset of cardiac failure. (9) With low systolic pressure decreased pulse pressure means general cardiac weakness, as seen in convalescence from long illness. (10) With high diastolic pressure a gradually falling pulse pressure means cardiac failure, as seen in the secondary low pressure of chronic nephritis. (11) With a high diastolic pressure and a moderate systolic pressure and the signs of cardiac decompensation, a rise in the systolic pressure is imperative to prevent failure. (12) With a high systolic, diastolic, and pulse pressure, arterial relaxants or vasodilators are imperative to relieve the symptoms of hyperplasia, *i.e.* hypertension, if symptoms manifest. (13) A rise of blood pressure is as surely a symptom demanding attention as a rise of temperature. (14) In the majority of cases

of shock a rapid fall of the arterial pressure occurs, and this is the best sign of shock, and a danger signal which cannot be safely ignored. (15) The best anesthetic is that which maintains the blood pressure at or near the normal level, with the least variation during the operation. (16) A high and rising blood pressure is an invariable and often the earliest sign of toxemia in the latter half of pregnancy. A pressure of 160 mm. systolic should always be regarded as highly suspicious. (17) In hemiplegia due to hemorrhage the blood pressure is always high; if due to thrombosis it need not be and seldom is high. (18) Perforation in typhoid fever causes a rise, hemorrhage a fall in pressure. (19) The early recognition of a rise in blood pressure is important in later life before any organic change has occurred and, therefore, while the case is amenable to treatment.

5. Goiter.—Leigh F. Watson presents an analysis of 125 cases of goiter together with a note on the treatment. He finds that both nontoxic and toxic goiters occur later in life in nongoitrous localities than in sections where the disease is prevalent. In this group of 125 patients the majority noticed increased symptoms of intoxication as the goiter became more chronic. Eighteen per cent. of the mildly toxic patients become exophthalmic after an average period of five years. In exophthalmic goiter 45 per cent. of the patients cured by quinine and urea injections gave a history of acute onset of symptoms while 54 per cent. had had goiter for some time previous to the exophthalmic symptoms, which were noticed at an average age of 37 years. The average time elapsing before the disappearance of the goiter was five months. In toxic nonexophthalmic goiter those patients who were cured by quinine and urea injections noticed symptoms of intoxication 1.7 years before examination, at the average age of 33.5 years. The goiter disappeared within from one to twelve months, the average period being four months. The number of patients cured was highest in the group of those who came for treatment early in the disease; the benefit received by those who came later was in proportion to the degree of damage done the circulatory and nervous systems. A goiter which has disappeared under this treatment has never recurred. The majority of patients in this group were under observation for from two to four years. Quinine and urea injections were used in treating 100 of these patients; in the remaining 25 this treatment was not judged to be suitable. This form of treatment is not suited to all types of goiter, and unless used discreetly will be disappointing, if not disastrous. The treatment of the exophthalmic type in young adults is most difficult, and should be attempted only under the most favorable circumstances. If the best results are to be secured hyperthyroidal patients must have at least a year of mental and physical rest after treatment.

1. Influence of Large Doses of Digitalis and Digitoxin on the Blood Pressures in Man.—Cary Eggleston reviews the recent literature on the action of digitalis and digitoxin and submits his personal observations on a series of fourteen hospital patients who were under complete control as to the conditions under which these drugs were administered. The averages for the three days before and the three days after the administration of digitalis have been calculated for the systolic, diastolic, and pulse pressures, and the heart rate for each case. An analysis of the results, taking all the cases together, shows that the administration of large doses of digitalis or digitoxin has very little tendency to elevate the systolic pressure, this having been increased by 11 mm. of mercury in one and 15 mm. in a second case. In only one case was the systolic pressure materially reduced, and in that instance by 23 mm. of mercury. On the other hand the diastolic pressure was significantly lowered in seven, or 50 per cent. of the cases, while it was never significantly raised. It is evident, therefore, that digitalis and digitoxin have very little influence on the systolic pressure in either direction, and that they tend to produce a significant reduction in the diastolic and, more decidedly, to produce a material increase in the pulse pressure. Further observations on this series of patients show that alterations in the pulse rate do not explain the changes occurring in the diastolic pressure, and that there is also a similar absence of relationship between the changes in the diastolic and systolic pressures. In view of the facts thus brought out it seems that there is no evidence that either digitalis or digitoxin has any direct action on the vessels when given to man even in large therapeutic doses. This agrees with the results of animal experiments which show that these drugs produce no vascular changes unless given in amounts several times those which are promptly fatal, or perfused through the vessels in concentrations much greater than could ever be reached in man. A consideration of the cause of systolic, diastolic, and pulse pressure changes leads the author to suggest that (1) Digitalis, by improving the circulation, leads to improved pulmonary ventilation with the relief of cyanosis and the abolition of the vasoconstrictor effect of carbon dioxide on the center. (2) The improved circulation results in the more normal functioning of the various organs and tissues of the body, and tends to restore to normal the several mechanisms by which the circulation is maintained at its most efficient level. This hypothesis fits in well with what is observed clinically.

5. Observations on Surgical Shock.—Yandell Henderson, A. L. Prince, and H. W. Haggard present a preliminary report undertaken at the request of the Committee on Physiology of the National Research Council in connection with a cooperative investigation of surgical shock instituted in a number of physiological laboratories throughout the country. These observers have chosen as their part of this investigation the following problems: (1) The bearing of excessive and prolonged secretion of epinephrin on the production of shock; (2) the relation of acidosis to shock, and (3) the oxidative metabolism in shock. They conclude that prolonged excessive secretion of epinephrin, if it occurs under pain, is not a critically important factor in the production of shock. It is therefore improbable that surgical shock is a result of the excessive secretion of the suprarenals secondary to sensory stimulation. In the investigation of the relation of acidosis to shock in all experiments with open ether anesthesia there was during the first hour the usual excessive breathing and a sharp fall both in the carbon dioxide content of the arterial blood and the carbon dioxide capacity of the blood, followed for several hours afterward by a less rapid but distinctly progressive and almost parallel fall in both measurements. The alveolar carbon dioxide also followed a closely similar course. There was a corresponding degree of shock as judged by fall of arterial pressure and absence of reflexes. In contrast to this in one experiment in

which ether was administered by a rebreathing method it was found that when excessive elimination of carbon dioxide was thus in part prevented both the carbon dioxide content and the carbon dioxide capacity (alkaline reserve of the blood) as well as the vitality of the subject were much less reduced than under "open" ether conditions. Facts brought out suggest that the acidosis of ether anesthesia is compensatory to or a result of the acapnia produced by the hypernea of ether excitement. In investigating the oxidative metabolism in shock the writers found that the condition of shock involves a profound depression of metabolism, the oxygen consumption falling 45 per cent. in one experiment and 50 per cent. in another. This depression of metabolism is progressive and ends in death. The introduction of the gas mask in warfare has accustomed men to a form of apparatus in which rebreathing can be readily arranged. By this means we may be able to get an adequate test of the very practical question, "Will rebreathing prevent or decrease the development of shock in severely wounded men as it does in animals under experimental conditions?" For those already in shock and breathing feebly, rebreathing involves a dangerous limitation of oxygen. In this condition the administration of normal percentages of carbon dioxide approximating the normal alveolar air is the measure which in the light of ten years' work in the laboratory is certainly worthy of trial.

6. **Botulism: The Danger of Poisoning by Vegetables Canned by the Cold Pack Method.**—Ernest C. Dickson, from a search of the literature and as a result of his personal investigations, finds that in all there have been at least twenty-two known outbreaks of botulism in the United States during the past twenty years, in which eighty-one persons have been ill and fifty-five have died, a mortality of 67.9 per cent. Of these twenty-two outbreaks eighteen have occurred on the Pacific Coast. The author believes that there have been many similar outbreaks of botulism which have passed without recognition. An important feature of these cases is the relatively small number in which the poisoning was caused by food of animal origin. He has examined a considerable quantity of fruit canned by the cold-pack method, in which fermentation has begun, and has found the *B. botulinus* present. Guinea-pigs inoculated with cultures from this source died within twenty-four hours. The symptoms produced were identical with those caused by the toxin of *B. botulinus*, which is formed in meat broth. The writer urges that, in view of the widespread advice to can all the vegetables possible, and the distribution of directions for cold-pack canning, all such products be thoroughly heated before being eaten or even tasted.

4. A Method of Applying Antiseptics to the Deeper Parts of Wounds. Thomas H. Kellock.

1. **The Physiological and Antiseptic Action of Flavine.**—Alexander Fleming sets forth in this article the result of some experiments which he has made with flavine in the research laboratory of a base hospital in France, which show that the claims that have been made that this substance approaches the ideal antiseptic are based on fallacious experiments, and that by altering the experimental conditions slightly the "therapeutic coefficient" can be altered to an enormous extent. He also shows that the action of flavine on human tissues (as exemplified by leucocytes) is far in excess of its lethal action on bacteria. In summarizing he states that flavine strongly agglutinates human red corpuscles up to a dilution of 1 in 3,200 and has a strong anticoagulant effect on human blood. In a concentration of 1 in 2,000 it completely inhibits leucocytic emigration. Flavine has a very destructive action on leucocytes, and if its action on leucocytes and bacteria be each tested for twenty-four hours its leucocidal action is far in excess of its bactericidal action. When many microbes are used it requires a much greater "lethal concentration" to effect sterilization than that given as the "lethal concentration" by Browning and his coworkers. In serum under certain conditions staphylococci will grow in 1 in 32,000 flavine, *B. coli* in 1 in 1,000, and *B. proteus* in 1 in 2,000. Flavine in 1 in 8,000 appears to aid the growth of *B. proteus*. Flavine in 1 in 500 is usually unable to sterilize in twenty-four hours an equal volume of pus from a wound. Injected intravenously in large doses it immediately disappears from the blood, which acquires no bactericidal power, and is taken up by the tissues, which acquire no inhibitory power on the growth of bacteria. Flavine 1 in 100 injected into the pleural or peritoneal cavities loses its antiseptic power within two hours. Flavine is rapidly absorbed by pus or muscle tissue. The socalled "therapeutic coefficient" can be changed with slight variations of the experimental method by at least 300,000 times.

4. **A Method of Applying Antiseptics to the Deeper Parts of Wounds.**—Thomas H. Kellock has made an attempt to improve on the Carrel method of irrigating wounds. He calls attention to the disadvantages of the Carrel method in that if there is much resistance to the exit of the fluid through the perforations in the tubes in the deeper portions of the wound the solution finds its way through the openings nearer the surface of the wound and hence the deeper parts are not reached. These tubes to a certain extent act as drains, and the pus finding its way into the tubes is washed back into the wound. Another disadvantage is keeping the patient still, since the slightest move on the part of the patient is apt to draw the tubes out of the wounds. Attempting to improve on this method the author takes a piece of drainage tube eight or ten inches in length and of a caliber about equal to that of a No. 8 catheter. The end is securely closed by a ligature and a small, oblique incision made with sharp scissors as nearly as possible to the closed end. The incision should cut a small valve with apex directed toward the closed end and should at its base divide one-third the circumference of the tube. The tied end should be inserted to the very depth of the wound and the free end of the tube left projecting through the dressings. The number of tubes used depends upon the size and character of the wound, but it will generally be found that one or two will suffice. In cases of a perforating wound of a limb or of a wound with two openings widely separated a very useful modification is to ligature the tube at its center and cut a valve on each side of the ligature and pointing toward it. This is passed through the wound and the irrigation done from both ends. In this way any fluid that is irrigated into the free ends of the tube must find its way to the very bottom of the wound and from there toward the surface. To secure the tubes in position a useful plan is to make a small, independent incision through the skin near the edge of the wound just large enough to grip the tube without occluding its lumen, and the free end of the tube is drawn through this. The free ends of the tubes are left outside the dressing, and the irrigating fluid is passed into them by means of a glass syringe.

1. **Remarks on the Treatment of the Wounded Knee Joint.**—H. G. Barling discusses the general results of treatment of wounds of the knee in the Rouen area from June to December, 1916, the figures from all the hospitals being added together, so that average results are obtained. The cases operated on numbered 845. All cases in which owing to the healthy appearance of the wound and the quietude of the joint no operative measures were resorted to, and also those cases in which conservative measures were impossible and early amputation was imperative have been excluded. The first feature that strikes one in these figures is the very high proportion of cases in which excision of the wound, re-

moval of bone when necessary, removal of any retained foreign body, irrigation of the joint, and closure by suture, has been followed by a perfectly satisfactory healing without further interference. The proportion of these cases requiring further intervention was 25.5 per cent. In those cases in which infection occurs aspiration is rarely a wise measure; three other courses are open to the surgeon: (1) Free opening up of the joint; (2) excision of the joint, and (3) amputation. By free opening of the joint the author means a lateral incision on each side to the extreme limits of the great bursal pouch and well to its lateral margins. The division of the lateral ligaments may be reserved until a later stage of ill-doing in the septic joint shows that it is really called for, and is to be resorted to especially when drainage of the posterior part of the joint is required. Dakin's fluid gives greater promise of successfully combating septic joints than any other measure, but it does not seem necessary or desirable to retain the tubes for an indefinite time inside the synovial sac. Whatever the method adopted for the opening of the joint its success will in the end depend upon the constant watchfulness and personal care of the surgeon. Excision of the joint is a procedure that has not been much in favor in the hospitals in Rouen. The writer has collected forty-two cases in which it has been been resorted to. Of these eight were followed by amputation, and the deaths, either with or without amputation, were thirteen. If excision is to be considered at all it must not be as an alternative to amputation. If the joint is excised very early we may get an immediate satisfactory result, but we do not know what the final results will be, and we shall be excising joints which in a considerable number of cases may recover under conservative treatment, some with useful movement. If excision is practised at a later period the death rate may be considerable, and there will be a high amputation rate and uncertainty as to the final utility of the limb in the remaining cases. As to amputation no one will dispute that early amputation would result in a low death rate, but it must be remembered that an ankylosed knee or a shortened limb is far preferable to an artificial limb. On the other hand it is a sad epitaph for any patient that his surgeon deferred amputation too late to save the patient's life. The percentage of amputations has varied considerably at the different hospitals. The total mortality from all cases has been 8.5 per cent. The highest mortality, 38.4 per cent., occurred in that group of cases in which the wound was excised and packed and a secondary operation was required at a later period.

5. **On the Treatment of Certain Selected Cases of Septic Arthritis of the Knee.**—W. Rankin believes that the problem of dealing with cases of this class resolves itself into doing an excision of the knee joint in two stages in suitable cases. To be a suitable case the following requirements are essential: (1) The patient must be young; certainly under thirty years, probably best not more than twenty-five years of age. (2) The favorable cases are lightly built men with small bones and without great muscular development. Fat and flabby cases are unsuitable. (3) The past history as regards general health must be good. (4) Courage and cheerfulness and a strong desire to keep the limb are most important factors. Querulousness and want of interest as to whether the leg stays on or not are contraindications. Excision should only be undertaken when there is likelihood that the case can remain in the same hands until bony union has taken place. The treatment is therefore best suited to the base hospital. The operation itself needs no description, consisting in the excision of the bone ends and the fixation of the limb on a splint which will allow the broad bony surfaces to lie in good apposition. The points to be looked to are that there must be no overstretching of the popliteal structures and no tension left in the space. Sufficient bone must be taken, yet none unnecessarily sacrificed. The guide is the circulation in the foot and toes, and proper attention must be paid to alignment of the middle line of the thigh and the tibial ridge and an endeavor made to get just a shade of hyperextension. An average shortening of 2 to 2½ inches can be obtained even with cases in which the excision has to be delayed for some months. Twenty-seven cases have been attempted from the summer of 1916 to the spring of 1917. Of these thirteen have been sent to England with good union, three are almost ready to proceed, and eight have died. Three were in the end amputated, all living. The average stay in the hospital was about four months.

La Presse Médicale.

The Cardiacs at the Front in 1917. — Aubertin mentions the fact that during the past three years of warfare large numbers of cardiac patients have been evacuated to the rear, from which the milder cases may be restored to the front after a brief course of treatment, while the organic cases are when possible utilized in auxiliary services. In this way the army has been largely freed from organically unsound subjects. There is a special type of soldier who appears at the heart station at the rate of about one a day. Some of these men even had their lesions before the war. This contingent seemed equal to full service at the front and their lesions escaped the regiment surgeons. Other members of this contingent who were probably more or less predisposed developed functional anomalies as a result of war hardships. In 100 of the combined group 30 were registered as having an aortic systolic murmur, while 28 others had tachycardia. As a matter of fact, only 21 of the 100 are recorded as having organic disease. In addition to the 100 cases the author considers 9 false cardiacs and 12 noncardiacs. The former are cardiophobes, robust men who fancy they have heart trouble, while by noncardiac is meant simply an error in diagnosis. Of the 100 patients, 6 had mitral insufficiency. These men were originally accepted after an "easy diagnosis" and later war hardships brought out the presence of the condition. Most of these men had, of course, been weeded out months before and were doing auxiliary duty. One man stayed at the front until dyspnea and edema developed. The small number of mitral insufficiency cases at the front is due largely to the fact that this affection is often badly compensated. There were 5 cases of mitral stenosis in the material which had originally been sent back as tachycardiacs. Other types of organic disease occurred only in isolated incidence. The 30 soldiers with aortic systolic murmur can be divided into two groups. One of these comprised but 5 cases in which some hypertrophy of the left ventricle was present with increased tension. In all of these subjects the murmur was loud. In the other 25 cases the murmur was slight and could readily escape the listener's attention. These men were sent back with the diagnosis of tachycardia or heart trouble, and only rarely of heart murmur. The murmur oftentimes could be heard only with patient recumbent, and over the ensiform cartilage. The blood pressure showed but slight variation and arrhythmia was not in evidence in the rapid pulse. After a few days of regimen these patients notably improved, although there was no change in the murmur. The nature of these murmurs is very obscure, but they are probably organic at least in part and the subjects will doubtless in time present ventricular hypertrophy, high blood pressure, and a loud murmur as in the group of 5 patients already indicated.

August 11, 1917.

Primary Tuberculous Ulcer of the Tongue. — These cases are sufficiently rare to be worth reporting. Amoroso's patient was a man aged 35, railway conductor. Parents healthy, but one brother died of tuberculosis. No history of syphilis. Wassermann always negative. About 4 years before, he had suffered from pleurisy. One year ago he noted the presence of a small vesicle on the left margin of his tongue. It resisted treatment and ulcerated, the sore gradually increasing in extent until treatment was sought. The lesion possessed all the qualities of a tuberculous ulcer, with but slight regional adenopathy, this excluding cancer. Without waiting for an exact diagnosis surgical intervention was practised. First the lingual artery was ligated above the level of the hyoid bone, while the enlarged submaxillary and precarotid lymph nodes were enucleated, much dissection being required to remove the deep submaxillary glands. The second stage

of the intervention consisted in excising a wedge from the tongue, including the ulcer-bearing area, in such manner that after suture the organ seemed almost intact. Studies of the ulcer showed the presence both of tubercle tissue and of Koch's bacillus. About 10 months later the patient was found to have pulmonary tuberculosis, as shown by sputum examination. He died in a few weeks of his disease, no particulars being related.

The Inventor of the Immersion Lens. — Ferrannini shows that Amici, an Italian, was the real inventor of this type of objective, for which Hartnach usually receives the credit. He was born in Modena in 1786. At the age of 22 he was professor of algebra and geometry in the local Lyceum. He had at the time the degree of laureate engineer architect, and soon removed from the Lyceum to the same chair of the local university. We next hear of him (1831) at Florence as astronomer to the Royal Museum of Physics and Natural History, and then as professor of astronomy at the University of Pisa. His work as an astronomer led him to a special study of optics and he superintended the manufacture of optical apparatus. In 1847 he was at work on homogeneous immersion lenses and in 1850 sent a specimen of one to Donders. He received due credit in several standard reference works of the day as the pioneer in this field. Chevalier of Paris, the well known discoverer of the achromatic microscope and local colleague of Hartnack, gave Amici full credit for the discovery of the immersion lens. The latter continued to work at the perfection of the microscope up to the time of his death in 1863. Despite all these data to support the priority claim of Amici several recent reference works award the honor to Hartnack.

Supravital Respiration of the Tissues in Fever.—Vernoni sums up his elaborate study as follows: in fever artificially provoked with living virus (bacteria) and in infectious fevers the respiratory activity of the liver is always increased. In fever from other causes this constancy is not observed. The behavior of the liver is due less to the fever itself than to the process of infection. The hepatic reaction is evident when the fever is decreasing, also in low and brief pyrexias. If the virus is concentrated in the hepatic tissue the reaction likewise occurs and evidently stands in relation with the destruction of germs in the circulation. In any case this participation of the liver is an index of its protective influence. Evidently there can be no fever of bacterial origin without this behavior of the liver. In addition to the liver the muscles show an increased gas interchange, and experiment shows that in this case also the reaction is not due solely to the pyrexia; because the amount of oxygen (Pflüger) necessary to raise the temperature of the body 1° C. was very much larger in the author's experiments (from 3- to 6-fold). But Pflüger's law applies only to the results of disturbance of the heat center (his experiment animals were either curarized or subjected to spinal cross-section). To account for the excess of muscular combustion in his experiments the author is forced to set up hypotheses such as action of the bacterial toxins on the nervous system, etc. We only know that fever due to living germs increases muscular respiration in some way over and above mere action upon the heat center.

On the Presence of B. Paraanthracis in Human Circulating Blood.—Maymone, having made studies of two cases, sums up as follows: The two cases seem to be of different types. In the first a typhoid infection was simulated, but the serorcaction failed on several trials, the paratyphoids could be excluded and the *B. paraanthracis* was cultivated from the blood. It is also known that mild forms of intestinal anthrax can simulate typhoid. The second patient actually did have a typhoid infection, yet the *B. paraanthracis* was cultivated from the blood into which it may have gained access through a typhoid lesion in the intestine. The course of the primary infection did not seem to have been aggravated by the presence of the paraanthrax bacillus, so that as far as the latter was concerned, the case must be regarded as one of latent microbism.

Correspondenz-Blatt für Schweizer Aerzte.

Dosage of Bromides in Epilepsy and Depressive Conditions.—Bernouilli calls attention to the comparatively recent use of bromides in melancholia, and to Ulrich's new method of producing a true bromide narcosis in depressive states. Under the influence of very large doses depression is changed to euphoria, whereupon the bromides are slowly decreased without relapse to the depressive state. Naturally a very precise technique is required lest the patient experience disaster. Our knowledge of the pharmacodynamics of bromides is imperfect in respect to the tolerance. Authorities tell us to increase the dose slowly up to a certain limit while keeping the patient on a salt-poor diet. Ulrich, however, has an entirely original conception of controlling the amount of sodium chloride ingested. He states this familiarly as follows: Suppose that the human body is represented by a bath tub, the bromide by the hot water supply and the chloride by the cold water supply. The tub is first filled to overflowing with cold water, after which cold water flows constantly in and out. The hot water faucet is now turned on with the cold, water continues to escape by the overflow pipe, but the temperature of the water slowly rises until a state of equilibrium is reached and the temperature now remains constant. This constancy is not affected by the amount of water which enters and leaves the tub, but if the hot water is shut off suddenly the temperature is slowly lowered until it reaches another constant level—that of the cold water supply. We wish to produce in the body a state of equilibrium between the two sodium salts which shall be analogous to the constant temperature of the bath tub water. To attain this result blood and urine analyses must be made at short intervals. The daily content of bromine in the urine furnishes a practicable control. The amount of sodium chloride ingested in the food is calculated from food analyses. To secure constant elimination of bromine by the urine, it is necessary to *increase* the amount of chloride daily for a certain period. On the first day the patient takes but 2 grams of salt in his food, but increases it progressively until on the tenth day he is taking 20 grams. The bromide is started at 0.6 gms. and increased in ten days to 6.2 gms. This gives a constant molecular concentration of bromine in the urine. If we begin with a larger dose—say 1.2 grams of bromide daily, increased in ten days to 11.8 gms., we obtain bromine equilibrium at a much higher concentration. When symptoms of bromide appear we then reduce the bromides and *reduce the chlorides*, too, at such a ratio as to keep the urinary bromine at an equilibrium. In other words the old ideas of salt deprivation are radically different in that they attempted to substitute bromides for tissue chlorides by reducing the latter at the expense of the former. With the old regimen, however, the aim was to prevent bromism; while Ulrich seeks to cause mild bromism, especially in depressive states. His bromine narcosis is characterized—in his depressives at least—by tipsy behavior, disturbances of coordination, vacillating gait, uncertainty in standing, disturbances in speech, writing and memory, and somnolence. This narcosis should not develop until several weeks of medication and should be allowed to reach a certain acme during which the withdrawal of bromide is begun. By cutting down the dose sufficiently the urinary bromine is seen to diminish, but should not leave the body entirely until after a long period of slow decrease.

Lichen Scrofulosorum from a Tuberculin Injection.—Brocq saw a well developed localized outbreak of this affection about the site of an intradermic injection of tuberculin.—*La Presse Médicale.*

Cerebrospinal Meningitis and the Weather.—Compton has shown beyond doubt that in saturation humidity with stable temperature and poverty of sunlight meningococcus carriers with germs in the rhinopharynx are prone to develop the disease.—*La Presse Médicale.*

Malarial Mammitis.—Carnot and Bruyère have seen five cases of this affection in malarial soldiers infected in Salonica. Its evolution is very slow and there seems to be no tendency to involution. The axillary glands show a reaction.—*La Presse Médicale.*

Book Reviews.

THE ROENTGEN DIAGNOSIS OF DISEASES OF THE ALIMENTARY CANAL. By RUSSELL D. CARMAN, M.D., Head of Section on Roentgenology, Division of Medicine, Mayo Clinic, Professor of Roentgenology (Mayo Foundation), Graduate School of Medicine, University of Minnesota; and ALBERT MILLER, M.D., First Assistant in Section on Roentgenology, Division of Medicine, Mayo Clinic, Fellow in Roentgenology (Mayo Foundation), Graduate School of Medicine, University of Minnesota. Price, Cloth, $6.00 net. Philadelphia and London: W. B. Saunders Company, 1917.

WITHIN the past few years the roentgenologic examination of the digestive tract has become a very efficient aid to gastrointestinal diagnosis; but, as the authors say in the preface, the extensive literaure of the subject has been widely scattered through periodicals and at the time preparation of this book was begun no effort had been made in America to collect the well-established facts into a single volume. Their aim has been "to select and arrange in a systematic manner those things which seem not only to be true but worth while, and especially those which we have verified by experience with a large amount of material." We may say at the outset that they have more than accomplished their aim as quoted above. They have not only collated all the essentials that could be drawn from the literature but have further enriched the subject by their contributions from material drawn from their own unusually extensive experience, and also have not hesitated to emphasize the lessons drawn from their own failures. Indeed, they have been especially frank in this regard, a fact which lends added credence (if that were necessary) to whatever statements they make regarding the more successful interpretations. There are twenty-eight chapters in the book, the first three of which are devoted to apparatus, general technic and interpretation. These are covered briefly, since there are other works devoted to this branch of the subject. The remaining chapters are devoted to the stomach, esophagus, and the individual portions of the intestinal tract, including chapters on the gallbladder and appendix. As many divisions of a field are made as seem necessary. Thus there are twelve chapters devoted to the stomach, so that besides considering the roentgen findings with the normal stomach and with the abnormal stomach in general, each special important condition, such as gastric cancer and gastric ulcer, is covered *in extenso*. The attitude of the author is eminently rational; for while properly interpreted roentgenologic examinations are of unquestioned value, the authors emphasize the fact that the roentgenologist is dealing with shadows and shadow defects and the dangers of faulty interpretation are great. There are few specialists in this line who could not profit by reading the short chapter on interpretation, for as the authors say: "The veteran roentgenologist, as well as the novice, is tempted to see too much rather than too little."

PRACTICAL MATERIA MEDICA AND PRESCRIPTION WRITING, with Illustrations. By OSCAR W. BETHEA, M.D., Ph.G., F.C.S., Assistant Professor of Materia Medica and Instructor in Prescription Writing, Tulane University of Louisiana; Formerly Professor of Chemistry and Professor of Pharmacology, Mississippi Medical College, etc. Second Revised Edition. Price, $4.50. Philadelphia: F. A. Davis Company, 1917.

THE chief value of this book is its essentially practical character, noticed especially in Part II, devoted to prescription writing—an art, incidentally, which is sadly neglected in these days of handy tablet preparations for every known human ill. Part I covers the field of materia medica with an alphabetical list of official and unofficial drugs, in the usual routine manner, taking up also their therapeutic action, uses, and customary methods of administration. In the case of the commoner and more widely used drugs, a variety of sample prescriptions are given, which we regard as a feature of value. In Part II the most approved methods of prescription writing are given, together with a discussion on the proper method of using the metric system, the employment of medical Latin, with correct abbreviations and other kindred topics, all of which is treated of in a clear, concise style, abundantly illustrated with appropriate examples. Part III takes up incorrect and correct forms in prescription writing and contains many good suggestions. An appendix is added which is devoted to problems and exercises regarding dosage, toxicology, etc.

The book covers 518 pages and is of a handy size. It is well printed and has a complete index arranged under two headings—Clinical and General. We recommend the book as a very satisfactory treatise on the subjects given in the title, being particularly adapted for student use and to the needs of the busy practitioner.

THE TREATMENT OF WAR WOUNDS. By W. W. KEEN, M.D., LL.D., Emeritus Professor of Surgery, Jefferson Medical College, Philadelphia. 12mo. of 169 pages, with 22 illustrations. Price, cloth, $1.75 net. Philadelphia and London: W. B. Saunders Company, 1917.

THIS book, compiled at the request of the National Research Council, gives a résumé of the most efficacious methods of treating war wounds. To a considerable extent it has been compiled from the writings of those in active service who have had unusual opportunities to note the value of the various methods.

After an introductory chapter devoted to certain general matters, including the arrangement of dressing stations, field and base hospitals, methods of transportation of the wounded, and treatment during transportation, the author proceeds with the discussion of special subjects. About twenty-five pages are given to the Dakin-Carrel method. Special chapters are also devoted to the removal of foreign bodies, tetanus, gas infection, and gas gangrene. Then follow chapters dealing with wounds of special regions, one on the treatment of burns and one containing extracts from personal letters from prominent surgeons who have had experience at the front.

The book should be of considerable value to surgeons about to have their first experience with war surgery, though it is far from being as exhaustive as might be desired.

DISEASE IN MILK, THE REMEDY PASTEURIZATION. The Life Work of Nathan Straus. By LINA GUTHERZ STRAUS. Second Edition, Revised and Enlarged to Commemorate the Twenty-fifth Anniversary of the Inception of the Work. Price, $2.50 net. New York: E. P. Dutton & Co., 1917.

THOUSANDS upon thousands of lives have been saved by the pasteurization of milk, and it may also be said that Nathan Straus by bringing pasteurized milk within the reach of the poor has saved a multitude of lives and greatly reduced infantile mortality in New York City. That Mr. Straus's work has been highly appreciated and its value recognized by men who have made a study of the milk question is demonstrated by the articles and letters which appear in this volume. It is eminently fitting that a comprehensive record of his beneficent labors should be presented to the public and to his wife all thanks are due for giving such a record to the world.

ASTHMA. Presenting an Exposition of the Nonpassive Expiration Theory. By ORVILLE HARRY BROWN, A.B., M.D., Ph.D., Formerly Assistant Professor of Medicine, St. Louis University. With a Foreword by GEORGE DOCK, Sc.D., M.D., Professor of Medicine, Washington University Medical School, St. Louis. Thirty-six engravings. St. Louis: C. V. Mosby Company, 1917.

THIS monograph is the result of nine years of study of asthma by Dr. Brown. He holds that the symptoms which are ordinarily observed in asthma are the outcome of the nonpassive expiration, of the factors that lead thereto, or of the conditions which result therefrom. According to the author, the strongest features of the theory are that preasthmatic states can be recognized thereby and successfully combated, and the treatment of asthma can be removed from the field of empiricism and put upon a rational and scientific foundation. The arguments in support of the theory are well propounded and the exposition of the methods of treatment is clearly and concisely set forth. The book throughout should prove of value to the active practitioner and medical student.

SECTION ON PEDIATRICS.

Stated Meeting Held March 8, 1917.

DR. ROGER H. DENNETT IN THE CHAIR.

The Emotional Life of a Child.—Dr. CLARENCE PAUL OBERNDORF read this paper. He said that many accurate descriptions of the emotional reactions of children had been written, but authors without attempting interpretations of their findings had been generally content with recording what they found. Broadly speaking, they all recognized that the emotional reactions in infancy were dependent upon pleasurable or painful sensations which the infant experienced as the result of his act. Thus Campayre wrote: "The first pleasurable sensations originate in the progressively moderate use of the organs of sense and the gratification of bodily wants." It was in the light of Freud's theories that they should view the emotional life of the child. Antedating Freud, in 1879, Linder called attention to the fact that the infant often practised suckling with an eagerness which completely absorbed its attention even though its appetite for food had been completely appeased. He also emphasized the fact that at times this suckling, independent of the appetite for food, was performed with a progressively increasing intensity, which culminated in a climax that resembled an orgasm. After such an episode the child often fell asleep, presumably as the result of gratification from this act in itself even when hunger was not in question. He even ventured the opinion that this act constituted a fleeting, transitional forerunner of future masturbation. Freud accepted this sexual conception of culminating suckling, but pointed out that the suckling was not primarily objective, that it was not derived from the action of the infant upon the mother, but was rather autoerotic, dependent upon the pleasure which the infant experienced from his own lip and mouth movements. The fulfilment of the culminative suckling was dependent upon the erogenous sensibility of the zone composed of the mucous membrane of the mouth and lips. Freud also agreed that the erogenous quality of the labial mucous membrane varied greatly in degree in individual children. He also described a double function to the evacuation of the intestinal tract. He asserted that the sensations which necessarily accompanied defecation were so agreeable to some children that they attempted to repeat them, or by "holding back" attempted to prolong the sensation. Dr. Oberndorf said it might be well to explain in discussing Freudian psychology that the term sexuality was used in its broad significance, and was not limited to the genital system. During the first months of life, according to the psychoanalytic school, the chief source of pleasure for the infant was almost exclusively dependent upon the movements of his own muscles, and from his own mucous membranes, and these latter were considered as of rudimentary sex significance. Intimately associated with skin and muscle eroticism, but appearing at a somewhat later date, was the pleasure won by the child from the earliest precursors of inflicting and submitting to pain, such as biting the breast, having its cheek pinched, etc. Although in very early life each of these tendencies was very meagerly developed, later they were definitely incorporated into the service of sex for the purpose of procreation. Perhaps if the baby could formulate its sensations after it emerged from the relatively undisturbed warmth and protection of the mother's womb, it would wish that "it had never been born." It was upon this basis that during critical emotional periods of later life the individual might be afflicted with pertinacious mother attachment, and might find definite fancies of solace and shelter which return to the mother's womb would afford. From these primarily instinctive processes were later developed acts of will. The will of the very young child always expressed itself in the act. Among the earliest expressions of infantile will was that of opposition to the will of his environment which so very soon clashed with his own. Even during the first year of life the child was compelled to suppress his will to such an extent that it was not surprising that outbursts of anger and defiance should appear. Here for the first time the parents came into contact with pedagogical problems, and it was evidently no easy matter to choose the correct balance between exaggerated strictness and excessive tenderness, both in the early years and in adolescent life. Children liked to be admired by their environment, and might be viewed in the light of an exhibitional trend, one of the most powerful traits of childhood. Another source of intellectual activity might be designated as sympathy or love. Intellect and emotion were especially closely connected in the child, and the sooner intellectual powers developed, the more intense was the emotional life. From the outline given it was evident that the child was occupied chiefly and unrestrainedly with the gratification of its own desires and necessities. It secured most of its enjoyment from the pleasurable stimuli it received from its own body or that was bestowed upon it by others. From the point of view of character development, this was of paramount importance, for it was very common to find this type of autoerotic emotional make-up persisting through late adult life, with the result that such individuals found themselves out of harmony socially with normal persons who had emerged from this stage through which all must pass. The cause of this maladjustment might remain quite unconscious to such persons, but their love life continued to center in themselves, or went one step further, and remained fixed on some one like themselves, that is, some one of the same sex. If this was true, it would seem from an educational standpoint that the early encouragement of responsibility for the child in contributing to as well as receiving from the family commonweal was desirable. What was new in this tiny phase of Freudian psychology was the complete conception of early acts in the pain-pleasure sense, their autoerotic value, and their precursory sex significance; also the persistent force in later life of early emotional impressions. Novelists from the early days of Fielding had hinted at many of these reactions, but perhaps nowhere had it been better expressed than by James Lane Allen, in his delightful idyll, "The Doctor's Christmas Eve," where he said: "The doctor wanted to be the first to talk with him (his son), the first to show the right suggestions." It was one of his sayings that the earliest suggestions rooted in the mind would be the final thing to drop from the dying man's brain—"What goes in first comes out last."

Dr. HERBERT B. WILCOX said that Dr. Oberndorf's remarks on emotion as applied to child life had rather inseparably coupled interpretation of such emotion with pleasure, in particular to pleasure of a sexual nature. Whatever the psychoanalytic interpretation of the term "sexual" might be, it must ultimately refer to elements which were, to his mind, as yet usually dormant in the patients of the age they were dealing with. Pure psychology had a small place in the activities of the pediatrician, excepting as it was applied by him to the parents with whom he dealt. Physiological psychology, as applied to the neuroses and habit spasms of children played a very important part in his work. Dr. Wilcox said he wished to take up the question of emotion in children and the influence upon their habits and routine life. Thumb sucking had really no relation to the question of food, or of sexual pleasure, or of emotion, although the child at first might suck his thumb because he unconsciously expected to get nourishment from the process. Before long, however, he learned the fallacy of this belief, and then the process of thumb sucking became purely a habit unassociated with the ingestion of food, and quite apart from any idea of erotic sensations. He had not seen the substitution of any of the less desirable habits for that of thumb sucking when the latter had been made mechanically impossible. The point had been raised with him at times by neurologists whose children he had treated as to the advisability of interfering with the habit of thumb sucking on account of the substitution of some other more serious habits in its place. It was, of course, quite possible that this occurred at times, but it had not been a factor in his experience. From our standpoint it was a question of the *abnormal emotion* influencing the *normal habit*. This applied directly to the suppression or prolongation of the act of defecation as being an emo-

tional element entering into and disturbing what should be an habitual response to a distended intestine, plus the increased peristalsis arising from the ingestion of food. It was clear that the matter of expulsion of the intestinal contents should be, and was under proper guidance, purely a matter of habit, occurring at a regular time, shortly after a meal, when, as was well known, peristaltic action was stimulated by a full stomach. The child up to perhaps eight years was, or should be, a creature of habit, a habit established from within; physiologically, from without governmentally. Habit and a more or less unquestioning submission to routine were the normal factors determining a child's reaction to his environment. When emotion entered too largely into his life, then he tended to become distinctly abnormal. There was no group of cases that offered more interesting problems of diagnosis, or presented more spectacular results, than those children who came to them because of a poor appetite, and suffering from constant irritation through urging, coaxing, and arguing at meal times, and who naturally presented as secondary symptoms bad assimilation, anemia, and digestive derangement. The basis of their trouble lay in the fact that they took their food under conditions of nervous unrest due to interference, and in the fact that they usually specialized on some type of food, thus throwing out of balance their food elements. Emotion had now entered meal time in this way. The child refused to eat from obstinacy, a very natural result of too much urging and coaxing, or later, because he emotionally enjoyed the attention he attracted. This illustrated the antipathy association spoken of by Dr. Oberndorf. So long as attention was attracted to him, so long he would strive to attract it and refuse his food. When the abnormal stimulus was refused, and he no longer seemed to know or care how much or how little he ate, he would find it dull playing the clown without an audience, and return to his habitual response to a physiological need.

Dr. WILLIAM B. NOYES said that two nights ago they had listened to a very remarkable paper by Dr. Glueck, who was making a study of the criminals at Sing Sing prison, and there was hardly a reference in the entire discussion to the development of the emotional life of the child. There were three methods of psychological study that they recognized: (1) The old-time method of distinguishing mental faculties as though they were in separate boxes, as attention, memory, judgment, emotions, volition, imagination, etc., a method which was less followed at the present time because they realized that all of the different mental faculties were so closely associated that they could not be thus separated. (2) The Simon-Binet method by which abnormal children might be distinguished from normal ones; by comparing the defective child with the normal standard for a given age we could tell what age the mind had reached. This method gave very brilliant results in young children, but after the child had reached the age of eleven or twelve years, it was not satisfactory. (3) The genetic method, or the study of the mind from the standpoint of development. All phases of delinquency, psychological and neuropsychological, were reviewed, but what was lacking and what the members of this Section would instinctively have grasped was a study of the characteristics in criminals and delinquents which every child, normal and subnormal, showed. In the criminal there were lapses or temporary returns to the mental characteristics of childhood. In the kleptomaniac or the person who played with fire we could trace the mental defect to a remnant of submerged sex conflict. Many of the mental conflicts that occurred after puberty might be traced by the psychanalyst to a submerged sex conflict, but there were many phases of delinquency which did not need the psychanalyst to interpret them; they were exaggerations of the emotional characteristics of the infant and the child with which every pediatrist was familiar. It was difficult to draw the line and to say just where certain characteristics ceased to be desirable and became abnormal. For instance, it was difficult to draw the line as to just where the spirit of loyalty to his friends in a boy ceased to be desirable, and degenerated into "gang spirit," which was the basis of much that was known as delinquency. Dr. Noyes stated that we were often hazy when it came to diagnosis, and we liked to follow sharp-cut labels. Thus frequently in discussing delinquency we used the term "instability." The French used the word "débile." A still broader psychological term was "psychological constitutional inferiority." While these terms might not be definite, they all harked back to the first three or four years of life. The unstable child might not be defective in brain structure and the essential mental faculties, but the unstable child would ultimately be shipwrecked if not controlled, and the time to control a child was about two generations back.

Dr. HORACE W. FRINK said he was much interested in Dr. Wilcox's remarks as to the necessity of establishing in the child proper habits of eating. From observations made from another angle, namely, the study of disturbances of appetite in the neurotic adult, he could confirm Dr. Wilcox's statements that every care should be taken to avoid getting the child in the habit of refusing food as a means of getting extra attention and sympathy. Dr. Frink said he wished to emphasize the fact that the term sexual as applied to such phenomena as thumb sucking and holding back of the feces had been given as the result of studies made upon adults who suffered from some evolution of the sex instinct—psychoneuroses or perversions. These infantile phenomena were named, not so much on account of what they displayed to the direct observation, as because of what in the pathological cases they might develop into. The term sexual as applied to them had, of course, a very different implication than was usually given to it in ordinary speech. The speaker also called attention to the fact that we need not be surprised by the statement that an organ, such as the mouth or anus, could serve two purposes, an alimentary and a sexual one. The same was familiarly true of other organs of the body, the eye, for instance, which, though it had a great many non-sexual functions, was nevertheless one of the most important sensory organs for the reception of sex stimuli.

Dr. FRANK WADE ROBERTSON said he might be old-fashioned, but he did not adhere so strongly to psychanalysis. He thought that in many instances we placed too much stress on apparently insignificant things. We could not always find out about the emotions of a child by judging them in accordance with the emotional standards of the adult. So far as the thumb sucking and the feces were concerned, he thought the thumb sucking was usually merely an incident in the child's life, and the questions brought up in connection with the feces he would explain by the fact that the child regarded defecation as a disagreeable duty, and put it off as long as possible, so as to continue his play, and he could not see the modern idea of sexuality in it. He said he had also another old-fashioned belief; he thought that probably sometimes a properly administered spanking would solve the problem and correct the bad habit. The parents were largely responsible for the emotional exacerbations of the child. If one took into consideration the emotional life of the present day, the absorption of the mother in social pleasure and excitement, and of the father in business, and the lack of cohesion or order in the family life, one would not be surprised that the child should manifest abnormal emotional traits. We should teach that there was no holier duty for a mother than to properly bring up her child and to impress her ideals on the child. We should remember that early impressions endured as long as life lasted, and it was most important that correct ideals should be cultivated from the first.

Dr. SAMUEL BANDLER said he had every intention of saying a few words, but the previous speaker in his last sentence had said everything he had in mind. The paper was very full of truths, some of which they had read and knew, and some that were new. This room should be full of physicians whose purpose it was to educate the public. Some were parents as well as physicians, and it was to the parents who were not physicians as well as to the physicians who were parents that a knowledge of the emotional life of the child was important, but he would like to ask if they were not failing to recognize the importance of heredity when they considered the emotional life of the child.

Dr. OBERNDORF, in closing, said Dr. Wilcox had brought up a question which was a very difficult one to solve in later life in people who showed neuroses, and that was the attitude of the parent. The parents of

the neurotic adolescent continued to be of the same mental caliber as when the child was born, and furnished the most difficult factor in the treatment of the young adult. The pediatrician had the opportunity to anticipate the psychiatrist and to instruct the parents in the dangers of excessive care early in the life of the child. Dr. Oberndorf again emphasized the point that thumb sucking was autoerotic, and cited an instance in which culminative thumb sucking was responsible for a tic later on in the life of a boy. In thumb sucking psychologically the pleasure was based on autoerotism; later on masturbation was a similar automanifestation, and he believed this was a normal transitional stage through which most children passed before reaching adult heterosexuality. Autoerotism varied with the individual, but he did not think heredity helped us to correct the present. So far as heredity was concerned, we must let that matter stand, and look to the future. What Dr. Robertson had said regarding the holding back of the feces as being an attempt to delay a disagreeable act, he thought that evacuation must rather be considered a pleasurable act. It would be a very unusual thing for a child to try to prolong a disagreeable act; children as well as adults usually avoided disagreeable acts. Concerning Dr. Noyes' reference to Dr. Glueck's work at Sing Sing, that would prove valuable principally as investigation rather than valuable in the sense of being beneficial to the individuals investigated. If Dr. Glueck's ability could be employed to help supposedly normal people solve some of their maladjustments, it would perhaps be of greater help to the community. The study of the criminal adult might yield some light on the best methods for meeting such tendencies in the very young. Dr. Oberndorf said that one of his favorite hobbies centered in the belief that the time would come when every high school child or even a common school graduate would be given a thorough overhauling psychologically just as he was now given a physical examination. This would be for the purpose of determining his fitness for a particular line of work, straightening out mental kinks, and of directing his future activities in life.

The Etiology of Mongolian Imbecility.—Dr. CHARLES HERRMAN presented this contribution. He stated that various authors had considered as important factors in the causation of Mongolian imbecility, worry, emotional shock, and disease of the mother during pregnancy. Many mothers of children showing those conditions, however, gave no such history, and a very large number of women who had trouble during pregnancy gave birth to perfectly normal children. Dr. Herrman presented the pedigree of a family which had come under his observation, in which the mother of the patients, J. G. and A. G., had been married twice. By her first husband she had one perfectly normal child; by her second husband, the first child was a Mongolian imbecile, the second a perfectly normal child, and the third again a Mongolian imbecile. The parents were both healthy, and the mother had been well during all four pregnancies; she experienced no worry or shock. Shuttleworth mentioned the case of twins, in which one child, the male, was normal, while the other, a female, was a Mongolian imbecile. In these instances it was hardly conceivable that a constitutional disease in the mother could be responsible either for the alternately normal child and the Mongolian imbecile, or that it could affect one of the twins and not the other. Immaturity or exhaustion of the generative organs, especially of the mother, had been given as a cause of Mongolian imbecility. It was true that a certain percentage of the mothers of Mongols were very young or very old; in about one-third the mother was over forty years of age. There were, however, about two-thirds in which the mothers were between twenty and forty years of age. On the other hand, large numbers of perfectly normal children were born to mothers over forty years of age, and there was no evidence to show that such children were weaker physically or mentally than those of preceding pregnancies. In about 50 per cent. of Mongols the child was the last of a series, though the Mongolian imbecile might come between two normal children, or be the first child. Adverse conditions affecting the maternal reproductive organs might possibly act as the predisposing, but they could not be the essential, cause of Mongolian imbecility. Pressure on the basal ganglia, as shown by the short antero-posterior diameter of the skull, the flat occiput, and the diminished weight of the cerebellum, pons, and medulla had been given as a cause of the condition, but here there was a possibility that there was a confusion of cause and effect. Congenital syphilis had been suggested, as a cause of Mongolian imbecility. The investigations of twelve authors representing a study of 3,872 cases of mental defectiveness showed 9.1 per cent. giving positive Wassermann reactions. There seemed to be no definite relation between syphilis and Mongolian imbecility either as regards the Wassermann reaction or the clinical evidence of the disease. Shuttleworth found clinical evidence of syphilis in only four of 350 cases. While frank cases of congenital syphilis were common, Dr. Herrman said he did not recollect seeing a single case which presented the manifestations of Mongolian imbecility, and he had had during the last eighteen years over one hundred cases of Mongolian imbecility under observation. Dr. Herrman discussed the possibility that syphilis might act primarily on some one of the endocrine organs, possibly the pituitary body, causing changes in the bones of the skull and face, but not all such changes were necessarily due to lesions in that organ. Postmortem examinations in Mongolian imbeciles had not shown any characteristic changes in the thyroid, thymus, or suprarenal bodies. The administration of these extracts in Mongolian imbeciles had not been followed by marked improvement. There was one feature upon which more emphasis should be placed, namely, the frequent association of Mongolian imbecility with other congenital anomalies. Besides the more common ones, congenital heart disease, strabismus, and anomalies of the palate, ears, fingers, and toes, Dr. Herrman said he had seen two cases of congenital cataract. There were comparatively few Mongolian imbeciles who did not show some anomaly. Many of these anomalies were known to be inheritable according to the Mendelian laws; many others were probably transmitted in this way. It was quite plausible that the association of these anomalies with Mongolian imbecility in the same individual was not merely a coincidence, but that the peculiarities of the brain, skull, and face were dependent on similar causes, and that they were inheritable according to the Mendelian principles. According to these principles, a "carrier" might be defined as an individual who had within him the peculiarity or unit character in a concealed, latent, or recessive form, so that, although apparently normal, he might transmit this characteristic to his offspring. Goddard's graphic charts had shown that the Mendelian theory had proven true as regarded feeble-mindedness. Goddard, however, did not include Mongolian imbecility in the hereditary form of feeble-mindedness, but thought its sole adequate cause was in the condition of the mother during pregnancy, yet it had been shown how unlikely it was that the condition of the mother during pregnancy was responsible. All observers had pointed out the difficulty of getting complete and accurate pedigrees. Dr. Herrman reproduced two pedigree charts of families with polydactylism. The first was that reported by Smith and Norwell (*British Medical Journal*, 1894, 11, 8); the second by Struthers (*Edinburgh New Phil. Jour.*, 1863, 28, 83). Polydactylism was an anomaly which would hardly escape notice, even though the child lived but a few days, and there would be no reason for concealing the fact that such a deformity had occurred, and still the two charts showed the greatest difference in demonstrating that polydactylism was an inherited unit characteristic. Two charts of Goddard's, an original and a revised form, showed how easily erroneous conclusions might be based on the original data in this instance. It must be remembered that abortions, still births, and deaths in early infancy, frequently occurred in the family history of Mongolian imbeciles, so that it was not at all unlikely that such a case was occasionally overlooked or unrecognized. In the 300 feeble-minded investigated by Goddard, 66 per cent. were classified as hereditary or probably hereditary, while only 11, or 3.6 per cent., were Mongolian imbeciles. These relative percentages corresponded well with those given by other authors, so that hereditary feeble-mindedness as classified by Goddard was about eighteen times as common as Mongolian imbecility. It was, therefore,

not surprising that the pedigree charts of Mongolian imbecility should not indicate inheritance so frequently or distinctly. The probability of the mating of two individuals who were carriers of this unit was much less than that of two individuals who were carriers of simple feeble-mindedness. It must also be remembered that one positive pedigree was more convincing and valuable than several negative ones. In one of Goddard's families and in three families which had come under Dr. Herrman's observations, there were two Mongolian imbeciles. Shuttleworth, Stevens and Hjorth (twins) had also reported cases. There was no positive evidence that worry, emotional shock, illness during pregnancy, or congenital syphilis were important or essential factors in the causation of Mongolian imbecility. The evidence that Mongolian imbecility was a unit character and recessive, although not conclusive, was suggestive.

Dr. CORA M. BALLARD said her observations in families in which there had been Mongolian imbecility was that in every branch of those families the majority of the children had various stigmata of degeneration. She felt that she could bear out Dr. Herrman's conclusions.

Dr. EDDY said he did not think that Dr. Herrman had proved much, because in looking through a family for any other condition, one always found some defect somewhere along the line. The mere association of Mongolian imbecility with those defects did not seem to him to prove anything.

Dr. WILLIAM B. NOYES said that Dr. Herrman did not mention hypothyroidism, and yet this condition was often marked in Mongolian imbecility. Many instances of cures were reported when thyroid extract was first used. This had been more recently tested out in Vineland, and while the hypothyroidism might be improved, the main condition of Mongolism remained unchanged. In general, Mongolian imbecility was a condition in which several stigmata of degeneration were in evidence in a definite and recurring combination in a low grade imbecile. Not all were present in every case. The slanting eyes, the brachycephalic head, the fissured tongue, short, pudgy, or pointed fingers, with the little finger abnormally short and crooked, were constant. Congenital heart disease and hypothyroidism were frequent. Sometimes two or three of these defects were present in a case distinctly not a Mongolian imbecile. The mentality might reach that of a high grade moron in rare cases. The figures quoted by Dr. Herrman were certainly quite convincing, and the association with the laws of heredity on Mendelian principles quite convincing also. The syphilitic origin as worked out in the Stevens list appeared plausible, but had not been confirmed in the cases seen in the Mental Clinic of the Department of Charities except in a few isolated cases.

Dr. HERRMAN, in closing, said that with regard to toxemia as a factor in the causation of Mongolian imbecility, about which he had been asked, he could not see how any toxemia could produce alternately a normal child and a Mongolian imbecile, nor could he see how it would be possible for toxemia to affect only one of twins. With regard to hypothyroidism and Mongolian imbecility, there was a time when these two conditions were confused, but we had now come to recognize them as two distinctly different conditions. There was no doubt but that in some cases of Mongolian imbecility a slight improvement had been brought about by thyroid medication, but such improvement was not marked or permanent. As to the fissured tongue, that was simply a question of sucking; excessive sucking first produced a prominence of the papillæ and then fissure. As to the last argument that there were defectives in all families, it might be said that the evidence in these instances presented was cumulative, and in time they might get enough to prove the position which he had taken; they had in one instance alternately a normal child and a Mongolian imbecile, and there were many defects in this family, among them three instances of congenital nystagmus and a case of deaf-mutism.

History of Pediatrics in New York. — Dr. ABRAHAM JACOBI presented this communication, in which he said that perhaps he had made a mistake in promising to prepare a history of pediatry in New York City, since he could not help speaking of himself in connection with that task, which included diet and hygiene predominately. Milk had been a serious study from the time we had nothing but the rotten milk of the Long Island manure heaps of sixty years ago, to the vastly improved secretions of to-day. Dr. Jacobi stated that the burning summer of 1854 furnished him with an experience which lasted forever in his memory. On leaving a dying baby, only one of his numerous victims of the murderous temperature, he met Dr. Joseph Kammerer and Dr. Henry Sweig, whom he asked in his despair what he was to do. Dr. Kammerer said: "You are killing your babies by feeding them on what we call milk; stop that." Dr. Sweig said: "Stop milk and everything else for twelve hours, or even a day; that is the only way for a possible recovery." He had learned from both men, and they had saved many babies for him The gospel of boiled milk had now found followers, and even prophets. We should not overlook the advantage pediatry, or rather one might say, the child world, owed to the indefatigable work of Mr. Nathan Straus, who in his own person had done more than he himself or any of us. Dr. Jacobi recalled his teaching with reference to cereal decoctions as an addition and corrective which had won many favorable criticisms and imitations. Likewise his teaching with reference to the use of cane sugar in the place of milk sugar was finding favor even in America. The gospel of fat feeding was no longer sustained by those who had a wholesome fear of acidosis, diarrhea, and indican; there were those who were satisfied with Jacobi's 2 per cent. fat mixtures, so long as the survival of the babies was the point to be sought. All these things Dr. Jacobi said he had taught in schools and papers and lectures long before 1870, and in a pamphlet which he prepared for the Board of Health in 1872; in a small book entitled "Hygiene of the Child," in 1874; in a larger book on "Intestinal Diseases," in 1887; in the first volume, 1875 and 1882, of Gerhardt's wonderful "Handbook"; in "Buck's Hygiene," etc. His treatise on "Infancy and Childhood" appeared in 1896, 1900, and 1903. He had been prevented from preparing new editions, and that was why he had stopped the sale of the book altogether. He was of the opinion that a few of the American textbooks that were really good satisfied the actual needs of the market. Personal ambition was not in his line; with the men who concocted books with the aid of other books he had little sympathy. Dr. Jacobi referred to the position he had taken with reference to the removal of tonsils. He had stated that tonsils were not always as dangerous as they were made out to be. Most of them might remain where they were. Too many tonsils were *exsected* in place of being *resected*. What was dangerous was the infection which took place from Waldeyer's ring. Dr. Jacobi said that he had taught sixty years ago, and was still teaching that children's noses and throats should be kept clean. Warm saline was the best cleanser. Boracic acid solution, rarely bichloride, 1:10,000, would sometimes take its place. No atomizer and no dropper, and only for certain indications a syringe, but rather a Whitall Tatum, No. 10 nasal douche, or for smaller children an E. Kretz Owen douche, was safe. There must be no snuffing up at any time; with these precautions the ear was not endangered. Potassium chlorate had been used and abused. Doses should be small and frequent. In stomatitis or in any of its combinations, even streptococcic, a child of three years might have from 15 to 20 grains in twenty-four hours. In diphtheria the same doses might be employed with tincture ferri chloride in water, and glycerin or syrup. Such combinations had long been sold as Jacobi's mixture by some apothecaries. The tincture should be administered in frequent small doses, ¼ to ½ to one drop, and not followed by water. Some had been studying infantile scurvy. But what he had often taught he had proved quite lately. He had taught that neither raw milk, nor boiled milk, nor pasteurized milk, nor carbohydrates, were the only or the prominent cause of scurvy; but what he had always urged was that the persistence of uniformity of food was responsible. Cow's milk and woman's milk were not uniform; proprietary foods were made to be so. Dr. Jacobi related a number of anecdotes showing the opposition that his efforts to improve infant hygiene met. The removal of heavy velvet curtains from the beds of babies, the advice to remove the clothing from babies while they were in the house in extremely hot weather, aroused a storm of protest. The recommenda-

tion to give babies one teaspoonful of whisky daily in a very hot summer was a crime from which he had never recovered, at least in the opinion of those who knew everything better.

SECTION ON SURGERY.

Stated Meeting, Held May 4, 1917.

DR. JOHN DOUGLAS IN THE CHAIR.

Metastatic Cancer of the Breast, or Axilla, Following Cancer of the Parotid Gland Six Years Ago.—Dr. ASPINWALL JUDD presented this patient, a woman who had been operated on six years ago for endothelioma of the parotid gland. She returned last August with a condition of the breast and axilla demanding operative interference. She had a high leucocystosis and a high polynucleosis. The glands of the axilla were broken down, soft and cheesy, but did not appear microscopically to be malignant. The report of the pathologist, however, stated that the condition of the glands was malignant, and of a rapidly growing variety. Last December the patient began to suffer with pain in her knee. When seen by the speaker the knee was enormously swollen and distended. A diagnosis of embolic process was made. The question that arose in this connection was whether the embolic process was also malignant and what relation it bore to the diagnosis of endothelioma. No malignancy was found in the breast.

Excision of the Hip Joint for Tuberculous Osteomyelitis; Conservative Method, Good Function.—Dr. JUDD also presented this patient, a boy, who he stated had no hip. This was one of a considerable number of operations of this kind which he had done. The boy had been operated on for a secondary infectious osteomyelitis. One by one, one ankle, one wrist, and one shoulder had been affected. He showed a high leucocytosis and was in an extremely emaciated condition. Dr. Judd stated that he had operated on one joint and then gone out of town, leaving the boy in another surgeon's care. When he returned he learned there had been no further operation, as the other surgeon considered the boy's condition hopeless. Dr. Judd then did a resection of the hip joint. The boy was now in good condition and had remarkably good function of the hip, though the joint had been entirely excised.

Excision of the Elbow Joint for Tuberculous Osteomyelitis.—Dr. JUDD presented a third patient, a young man, whom he stated had no elbow and who, nevertheless, had a strong grip and practically perfect function. There was nothing particularly new about the operative procedures in these cases. He did the simplest operation consistent with the removal of diseased bone, leaving the periosteum and the muscular attachments. The bone in such a tuberculous condition must be cleaned out thoroughly, but he was willing to take a small chance on the periosteum in order to conserve the muscular attachments. He endeavored to keep the fistula open, packing it with gauze and leaving it for five or six days, then removing the packing and repacking. This had to be done under anesthesia, as a rule. His object in keeping the wound open was to secure as much granulation tissue as possible. The *x*-ray showed the radius intact and that the end of the humerus had been removed. The important point in these operations was the conservation and adjustment in their proper relations of the muscular attachments.

Infection of the Knee Joint (Gas Bacillus).—Dr. JAMES W. JAMESON presented a man who had run a tack into his knee early in the morning. The same evening he was admitted to the hospital with a temperature of 102.8°, and pulse of 90. His right knee was swollen, hot, very tender on pressure and also in active and passive motion, and the joint contained considerable fluid. White blood cells were 15,800. He apparently had a severe infection. Under cocaine the joint was aspirated and about 75 c.c. of thin, turbid, yellowish fluid was removed, after which the joint was washed out with ½ per cent. carbolic acid solution. No traction was used. The patient's condition immediately improved, and his temperature gradually fell, in three days reaching 100° F. He was discharged at the end of ten days with a slight swelling of the knee, but complete function. Later he developed a phlebitis, which soon cleared up. The smear from the fluid showed many pus cells, Gram-positive diplococci possibly streptococci, and anaerobic cultures showed the *Bacillus aerogenes capsulatus*. *X*-ray was negative. Case was presented to show the excellent result of treatment in the presence of gas bacillus.

DR. E. BENJAMIN RAMSDELL said that gas bacillus infection was very prevalent in war surgery and that he had seen many cases in France. A culture was taken of every wound that came into the hospital and incubated in veal medium. If the gas bacillus was present it would be evident in a few hours. If the gas bacillus got into the muscle tissue the infection was likely to be more serious than elsewhere.

Bilateral Astragalectomy and Tendon Transplantation for Paralytic Club Foot.—Dr. ALFRED J. BROWN presented this case. He stated that the patient, 26 years old, was admitted to the hospital on May 12, 1916. He gave a history of having been able to walk normally until eleven years previously, when he had a sickness which he described as rheumatism. Following this he was unable to walk for a year. He entered the hospital because of great difficulty in walking and continuous pain in the ankles. The diagnosis made was talipes equino-varus, resulting from infantile paralysis. Both legs showed atrophy of both muscle and bone and disturbance of function. On May 18 an astragalectomy was performed on the left side. The procedure employed was as follows: An incision was made beginning beneath the tip of the external malleolus running forward and downward to the point of attachment of the peroneus tertius muscle. This was deepened down to the ligament of the ankle joint. The external lateral ligament of the ankle joint was divided, also the anterior ligament of the joint. The astragalo-navicular joint was opened and also the astragalo-calcaneal joint. The interosseus ligament between the astragalus and the os calcis was divided. The astragalus was lifted out of the wound, and the ligaments of the inner side divided in order. The astragalus was removed. Subcutaneous dissection was carried to the inner side of the foot and the tendon of the tibialis anticus muscle isolated and split longitudinally, the outer half of the tendon being divided at its point of insertion by a subcutaneous tenotomy and pulled over to the outer side of the foot and anchored beneath the periosteum of the cuboid bone. The skin was closed with silk, and a dry dressing applied. A plaster of Paris casing was applied from the toes to just below the knee, holding the foot at right angles to the leg and in a position of eversion. On May 25 a right astragalectomy was performed. The technique was the same except that the entire tibialis anticus tendon was transplanted. The plaster dressing was removed and reapplied on June 15 and July 13, the latter time with wooden soles. The patient was discharged on August 29. At the present time the patient walks fairly well. He has never worn braces. The joint on the right side was not as good as that on the left.

Dr. S. EPSTEIN said he thought if the cartilage had been removed from the under side of the fibula and tibia the joint would have been more stable.

Dr. BROWN said that he did not try to get an ankylosis and consequently he had not tried to remove the cartilage from the under side of the tibia and fibula.

Dr. A. SULLY objected to leaving in cartilage from the astragalus as Dr. Brown did not want to get ankylosis. He did not believe that Dr. Brown's procedure was one that should be repeated.

Appendicitis Recurring in a Stump after Operation.—Dr. ALFRED J. BROWN reported this case. He stated that the patient, a girl 15 years of age, was admitted to the hospital on November 22, 1916. She gave a history of having had an appendectomy performed in another hospital on August 4, 1913. She was discharged from the hospital two and one-half weeks after this operation, and a few days later was seized with an attack of sharp, sticking pain in the right side, radiating to the back and so severe that she was forced to go to bed. She remained in bed for a week. Two days after her recovery she was seized with another attack. Since that time these attacks have been intermittent and accompanied by vomiting. She was operated on December 9, 1916, in the first Surgical Division, Bellevue Hospital. The great omentum was found adherent

to the anterior surface of the cecum, causing an angulation of the right half of the transverse colon. The cecum was adherent itself by fairly strong membrane to the right abdominal wall. The appendix stump was approximately two and one-half cm. in length, turning backward and adherent to the inner surface of the cecum. From its tip there was a strong fibrous band of adhesion pressing to the iliacus muscle. The operation performed was as follows: A right rectus incision eight cm. in length was made and deepened through the peritoneum. The adhesions between the cecum and the great omentum were divided and the transverse colon freed. The adhesions between the cecum and the lateral abdominal wall were ligated and divided, freeing the cecum. The mesentery of the appendix was ligated with plain catgut. The band of adhesion between the appendix and the lateral abdominal wall was divided. A purse-string of Pagenstecher linen was passed around the base of the appendix. The appendix was crushed between Kocher clamps, removed, and the stump cauterized, inverted and the site of eversion protected by a continuous Cushing stitch of plain catgut, inasmuch as the mesentery was too small to allow of the usual technique practised by the reporter. The wound was closed. The patient made a rapid and uneventful recovery. The pathological diagnosis was chronic appendicitis. The patient was shown for the purpose of demonstrating the complication which might occur with that type of operation if one failed to invert the stump. Dr. Brown emphasized the importance of the following points: Crushing the stump of the appendix and cauterizing down to the proximal clamp, using a dull-red heat to close the stump. Placing a suture of Pagenstecher linen which passed beneath the vessels on the mesenteric side to control hemorrhage when tied. The knot of the Pagenstecher should be opposite the mesenteric border. The stump was here riveted without opening the lumen of the gut, and thus infection of the field was avoided. If the proximal ligature on the mesentery had been left long, tying this to the ends of the Pagenstecher linen pursestring suture would draw the mesentery over the site of inversion and protract it.

Dr. HENDERSON said he had seen three hemorrhages and thought it was better to ligate close to the base, no matter what technique was used. If that had been done there would have been no recurrent attacks.

Dr. JOHN C. A. GERSTER said he agreed with Dr. Jameson that this case showed an error in technique at the first operation. He had seen a similar case where it was reported that the appendix had been removed some time previously; the patient showed typical symptoms of an acute appendicitis and an appendix about two inches long was found beneath a pericecal membrane. This illustrated failure to trace the appendix down until it began to flare into the cecum. The simple ligation of the appendix with cauterization of the stump had been the routine practice at Mount Sinai Hospital since the very begininng of operations for this condition. Bad results have not been seen, provided the proper technique has been employed. In one instance the actual cautery was brought too near the ligature, it became cooked and gave way with leakage and fatal peritonitis. In another instance a ligature of heavy silk (instead of heavy plain catgut) was used. A few months later a band leading to this ligature caused an intestinal obstruction; at the time of its division the silk ligature was removed. Pure carbolic has satisfactorily replaced the actual cautery, thus eliminating the possibility of cooking the ligature.

Neurotization of Paralyzed Muscles by Implantation of Motor Nerves. — Dr. JOHN C. A. GERSTER reported having successfully innervated paralyzed muscles by implantation of motor nerves previously supplying other muscles. (See MEDICAL RECORD, August 11, 1917, page 223)

Dr. ROBERT T. MORRIS asked Dr. Gerster how he would account for the return of sensation in a case such as he had seen some time ago. In this instance a girl had had her arm and hand very badly crushed and he had implanted three fingers at about the middle of the forearm. Finally this girl developed sensation in these fingers, first for cold and after for heat. She knew when the fingers were touched but was unable to tell which of the three fingers had been touched. In what way were these fingers innervated?

Dr. BROWN asked Dr. Gerster if he had ever tried this on human beings, or if he had seen any cases in which it had been tried.

Dr. GERSTER, in closing, said Dr. Morris' case illustrated the return of sensory function. As to the possible clinical value of neurotization of recently paralyzed muscles, it would probably be of distinct value in selected traumatic cases not amenable to nerve suture, etc. In poliomyelitis certain difficulties presented themselves; first, the late recovery of muscles—orthopedists claimed that it was not possible to decide what muscles were paralyzed before 12 to 18 months had passed—some very atrophic muscles would begin to regain power as late as that; on the other hand certain neurologists had thought it possible to tell within 3 or 4 months which groups were going to recover. If one waited until the matter was absolutely decided, the far gone atrophy furnished less favorable conditions. If one operated before then, it might be said that recovery had occurred in the natural course of events and had no relationship with the operation. In addition to this one would be taking away a part of the healthy nerve supply (lessening it) to give a paralyzed group function. In case of failure, the limb would be even weaker than before. The clinical reports so far were inconclusive. The speaker said he had had no experience with innervation by contact of paralyzed muscular tissue with normally innervated muscle—the so-called muscular neurotization. Such a procedure would be far less risky in poliomyelitis cases, for a simple removal of intermuscular septa between healthy and paralyzed muscles might permit of nerve fibrils growing into the non-innervated muscle. There would be no disturbance of normal innervation. Failure would entail no additional loss to the patientt.

Books Received.

The MEDICAL RECORD *is pleased to receive all new publications which may be sent to it, and an acknowledgment will promptly be made of their receipt under this heading, but it must be with the distinct understanding that it is under no obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.*

ORTHOPEDIC SURGERY. By ROYAL WHITMAN, M.D. 906 pages, illustrated. Published by Lea & Febiger, Philadelphia and New York. Price, $6.50.

EXAMINATION OF WATER. By WILLIAM P. MASON. 186 pages, illustrated. Published by John Wiley & Sons, Inc., New York. Price, $1.25.

THE CHILD IN HEALTH AND ILLNESS. By Dr. CARL G. LEO-WOLF. 297 pages, illustrated. Published by George H. Doran Company, New York. Price, $2.00.

DELUSION AND DREAM. By Dr. SIGMUND FREUD. Translated by HELEN M. DOWNEY. Introduction by Dr. G. STANLEY HALL. Published by Moffat, Yard & Co. 243 pages, illustrated. Price, $2.00.

DISEASES OF THE SKIN. By RICHARD L. SUTTON. 1,021 pages. Published by C. V. Mosby Company, St. Louis. Price, $6.50.

THE PRESCRIPTION. By OTTO A. WALL. 274 pages. Published by C. V. Mosby Company, St. Louis. Price, $2.50.

MEDICAL WAR MANUAL, NO. 1. Sanitation for Medical Officers. By EDWARD B. VEDDER, M.D. 211 pages, illustrated. Published by Lea & Febiger, Philadelphia and New York. Price, $1.50.

THE BATTLE WITH TUBERCULOSIS AND HOW TO WIN IT. By D. MACDOUGALL KING, M.D. 258 pages, illustrated. Published by J. B. Lippincott Company, Philadelphia and London. Price, $1.50.

AN INTRODUCTION TO THE PHYSIOLOGY AND PSYCHOLOGY OF SEX. By S. HERBERT, M.D. 136 pages, illustrated. Published by A. & C. Black, London; The Macmillan Company, New York. Price, $1.25.

CLINICAL CARDIOLOGY. By SELIAN NEUHOF, B.S., M.D. 302 pages, illustrated. Published by The Macmillan Company, New York. Price, $4.00.

THE PRINCIPLES AND PRACTICE OF DERMATOLOGY. By WILLIAM ALLEN PUSEY, A.M., M.D. Third Edition. Published by D. Appleton & Co., New York and London.

AN EPITOME OF MENTAL DISORDERS. By E. FRYER BALLARD. 211 pages, illustrated. Published by P. Blakiston's Son & Co., Philadelphia. Price, $2.25.

Miscellany.

Suicide Mortality Among Wage Earners in the United States.—The Metropolitan Life Insurance Company has recently completed a study of suicide as a cause of death among the Industrial policy-holders of the Company. According to this study there has been a marked decrease in the death rate from suicide during the last few years. Among four million insured white males the number of suicides in 1916 was 620, or 15.3 per 100,000. In 1915, the rate was 19.6 per 100,000. The most frequent form of suicide among these white males was by firearms (31 per cent.). Among nearly five million white female policyholders, there were 308 suicides in 1916, or 6.3 deaths per 100,000 insured. In 1915, the rate was 7.5 per 100,000. Poisoning was the most usual method of suicide among the white females—more than one-third having been so accomplished. The death rate from suicide among negro males is a little over one-half as high as among white males. In 1916, the rate was 8.2 per 100,000 insured. Negro females show the very lowest rates of any of the groups studied. The rate was 3.4 per 100,000 in 1916, the total number of suicides being only 22 among over 650,000 insured colored women.

Rat-bite Fever.—The febrile condition occasionally following the bite of the rat is of special interest at the present time, when the rat is a constant companion of the man in the trenches. Dr. T. J. Horder, in the *Quarterly Journal of Medicine* for January, 1910, described three cases of irregular periodic fever following the bite of a rat, and to these Dr. G. S. Middleton added a fourth in *The Lancet* of June 11, 1910. In a brief note on rat-bite fever in the "Medical Annual" for 1913 Dr. F. J. Charteris describes the characteristic sudden attack of fever repeated at intervals of a few days, each attack being ushered in by a rigor. He states that in a number of cases salvarsan was used with apparent benefit, seeming to cut short the disease.

Dr. Herbert French, in a later number of the "Annual," also calls attention to the periodicity of the febrile attack, which recalled to him some of the characters of relapsing fever. We shall hardly be wrong in assuming that rat-bite fever is in fact due to an infecting organism, although as yet no one has succeeded in isolating it. We should like, however, to suggest that the type of temperature chart in all the cases we have cited of this fever is curiously reminiscent of the charts of trench fever given by Major Arthur F. Hurst, R.A.M.C., in *The Lancet* of October 14, 1916, and of the charts of the Volhynian fever, described as occurring in the German trenches, especially on the Russian side, of which we gave examples in *The Lancet* of March 3. No one, as far as we know, has claimed that trench fever is due to the direct bite of the rat, but the opinion is gaining ground that it is a spirochetal disease conveyed indirectly by a parasite from animal to man, and that the rat is the animal to blame. Rat-bite fever and trench fever may differ only in the presence in one case of an intermediate host. There should be opportunity in the trenches for a comparative study of the two fevers.—*The Lancet.*

Therapeutic Hints.

Malaria in Children.—William H. Deaderick states that in the treatment of this condition in children the best practice is to administer the quinine at short intervals, every two or three hours. While children bear quinine in relatively large doses better than adults, the size of the dose should be regulated by the severity of the attack and the age of the patient. In average cases children from six months to two years of age may be given from one-half to one grain of quinine every three hours; from three to five years, one to two grains; from six to ten years, from two to 2½ grains. These quantities may be increased in severe attacks. The drug is usually given by mouth and where capsules cannot be used, the drug must be given in a tasteless preparation or a disguising vehicle. Euquinine and tannate of quinine are the best tasteless preparations. The former must be given in slightly larger doses, the latter up to double the dose indicated above. The most efficient liquid for disguising the taste of sulphate of quinine is syrup of yerba santa, at least one dram to be given for each two grains of the quinine. In pernicious malaria the drug should be injected intramuscularly in dilute solution and the best salt for this purpose is the dihydrochloride. Intravenous injection is preferable but the veins of young children are often difficult to penetrate. Rectal administration of the solution or suppository may be employed to supplement other methods, and the buttocks should be pressed together for one-half hour after insertion to aid retention. Inunction of quinine and lard, as employed in the South, may be used as an additional means.—*Interstate Medical Journal.*

Paludism.—Green offers the following formula for use in malaria:

℞ Acidi arsenosi .....0 grams .10
Quininæ sulphatis .....4 grams.
Confectionis rosæ .....2 grams.
M. et ft. in pilulæ No. xxx.
Sig.: Two pills to be taken each day.—*Bulletin Général de Thérapeutique.*

Vomiting of Pregnancy.—C. R. Hannah considers the following measures decidedly beneficial in this condition: In the reflex type correct any malposition of the uterus, remove tumors, or a troublesome appendix and treat and restore to normal function any offending organ. In the neurotic type, ascertain home surroundings and endeavor to correct difficulties, improve home hygiene and put into practice rigid suggestive therapeutics. Cooperation of family and firmness of doctor are needed here. Elimination by bowels and free use of water per anum are excellent; also dilatation and application to the cervix are means of good mental suggestion, when needed. In the toxic variety, drugs have often failed. Adrenalin sometimes gives relief. Hannah has had greater success by insisting upon the patient taking her breakfast in bed and remaining there for one or two hours; eating whatever she wants at any time during the day and even immediately after vomiting; giving large doses of sodium bicarbonate (one dram to eight ounces of water) six times a day, and by making a thorough vaginal examination, and, if normal, letting the patient alone.—*Texas Medical Journal.*

OSMOSIS, AN IMMUNIZING FACTOR IN TUBERCULOSIS.

BY P. SANFORD BAILEY, M.D.,

FORT BAYARD, N. M.

THEORIES, speculations, hypotheses, are started; in exceptional instances only are they deemed worthy of prolonged or permanent adoption. And so it is that while offering the following interpretations of the osmotic phenomena and attempting to indicate those phenomena as immunizing factors in pulmonary tuberculosis, I am perfectly conscious that such a thesis may be beset with many snares.

However, if we start from fixed points, making our ground good as we go, by collecting only the best of evidence, new lines of thought or conquest may be suggested and I conceive we shall arrive at values of no inferior kind.

A little difficulty may attend an effort to coordinate sufficient evidence in a limited paper to illustrate clearly a probable relation between such complex and imperfectly understood phenomena as osmosis and immunity in pulmonary tuberculosis, and yet, that osmosis might be, and probably is, the value to assign the several unknown quantities in the perplexing equation of immunity in tuberculosis, there is no substantial fact which I am able to discover that can be adduced to prove the contrary.

That the phenomena of osmosis should be assigned by nature to the important task of largely maintaining the processes of growth, reproduction, assimilation, and repair, or in a single word, life, and yet are not in some manner endowed with potential energies to counterbalance and resist invasions against life, would indeed be a biological paradox. The truth is, as we shall discover, there is considerable evidence to sustain in whole or in part the theory of an intimate dependency of immunity upon osmosis in pulmonary tuberculosis.

To qualify properly the several points which are to follow, it may not be out of place here to present a few of the more essential facts concerning our accepted ideas of immunity. The magnitude of the subject, however, combined with a necessity for being brief, makes it impossible to consider anything more than a relatively incomplete, elementary review. For a more extensive study of the subject reference must be made to more complete sources.*

*Consult: "Studies on Immunity," by Ehrlich; "Studies on Immunisation," by Wright; "Immunity in Infective Diseases," by Metchnikoff.

The almost universal attention which is centered upon the perplexing problems of susceptibility and immunity, natural or acquired, in tuberculosis, is evidence of the fact that there is no more interesting or more important question in the whole domain of biology.

Immunity may be broadly defined as the state of physical security possessed by individuals or species whereby they do not give evidence of a reaction or disease when the poisons which cause such reactions or diseases in other individuals or species are introduced within their organisms.

Immunity should be accepted rather as a relative term, for all organisms are more or less susceptible to reaction under certain circumstances to some form of bacteria and their poisons. Conversely, all animals manifest a tendency to resist bacterial invasion and it frequently happens that this resistence is sufficiently effective to secure the body against many specific forms of bacteria which succeed in entering the organism. Not infrequently an entire race of people have manifested this quality of resistence to certain pathogenic microorganisms; yet, again, there may be an unusually high degree of susceptibility in a people even to the less harmful forms of bacteria. Racial immunity is probably acquired only after repeated or prolonged exposure through several successive generations to the same pathogenic bacteria. As an instance of this racial susceptibility and immunity, the once powerful Indian nations which flourished in early colonial days, in New England, may be mentioned. The Indians perished by thousands from a fever to which they were formerly strangers and which the Europeans who nursed them never contracted.

In so far as individuals are concerned, resistance to bacterial infection seems to be a very variable quantity. Every physician is quite familiar with many instances, even in the same family, of individual tendencies either to resist prolonged exposure to infection or in other cases to evince a marked susceptibility.

Together with the differences in racial and individual immunity and susceptibility, the various organs of the body are influenced in varying degrees by the controlling factors of resistance. No satisfactory explanation has as yet been given for these apparent differences. The lungs, especially in the instance of tuberculosis, are undoubtedly the organs of least resistance. The other organs of the body, more particularly the muscles, seem to possess a relatively high degree of immunity to tuberculous infection. That the lungs are the first to manifest the presence of primary tubercles there can be no doubt; yet the other organs of the body

rarely, or only in extreme cases, evidence tuberculous involvement.

Resistance or susceptibility to pathogenic bacteria may be either a natural inherent quality of a race, individual, or organ, or this natural immunity or susceptibility, as it is respectively designated, may be increased or lessened by various causes, and in such instances it is usually known as an acquired immunity or susceptibility as the case may be.

There are many reasons for believing that the factors which influence these transformations are not the same in all cases, for they frequently are known to vary for the same or different individuals from time to time under conditions which, in the instance of tuberculosis, are quite imperfectly understood.

It is probable that these essential differences depend in most instances upon conditions which tend to encourage or to prevent the development of pathogenic bacteria; or upon the destruction of those bacteria by some property residing in the tissues or fluids of the body; or upon a neutralization of their toxic products by certain substances in the bodies of those individuals who have sufficient immunity to overcome infection.

It is of some importance to distinguish the difference between natural and acquired immunity. Certain defensive proteins of germicidal power seem to be found only in the blood serum of the naturally immune; they have been designated as alexins to differentiate them from the antitoxins of acquired immunity which they somewhat resemble.

The simple fact that pathogenic bacteria not infrequently find unsuitable metabolic conditions in some individuals or species would seem to account in some measure for the natural immunity in these cases; while again, successive accidental inoculations in some animals may also be a possible factor. Examples of such instances may be mentioned in the extreme immunity to tuberculosis evidenced in fish, frogs, turtles, etc., while the larger carnivora are also notably immune. The supposition in the latter instance is that the carnivora which quarrel over the dead bodies of herbivora which are especially prone to tuberculosis have, through the infliction of wounds in combat, successively inoculated themselves for many generations and are in consequence thereof no longer susceptible. As an example of marked susceptibility the inevitable guinea pig may be mentioned.

Instances of a natural individual susceptibility to tuberculosis are frequently seen when, from among several children of equal inheritance in a family, and similar environment, one of the children only will evidence insufficient immunity to resist the disease.

However, no individual, race, or species is known to possess absolute immunity to the tubercle bacillus.

Acquired immunity may be either active or passive. Active acquired immunity is induced by a direct stimulation of the cellular elements of the organism through the introduction of a specific reaction by inoculations, one or several, with virulent bacteria, bacteria attenuated in virulence, dead bacteria, or the products of bacterial proliferation. Such specific reactions are probably induced at some expense to the whole organism for they are quite the same as the disease against which protection is desired, although more mild in degree. Nevertheless, in the special instance of vaccination against smallpox, all of the facts certainly do not seem to justify the misinformed forces leagued against this valuable measure.

Passive acquired immunity neither induces a specific reaction nor the stimulation of the organism to the production of its own protective substances. On the contrary, these reactions and substances are simply produced in the body of another animal and from this the individual to be protected is subsequently injected with the immunizing serum thus formed. The production of diphtheria antitoxin by means of inducing the specific reaction in the horse and later transfering a small quantity of the serum to the individual requiring that specific immunization is an illustration.

The researches of Pasteur, Toussaint, Koch, and other investigators in this field of biology constitute the foundation of our present knowledge of bacteriology, protective inoculations, serum-therapy, and the mechanism of immunity.

Originally it was supposed that the specific reaction or disease which was manifested when pathogenic bacteria in sufficient numbers formed a focus in the body, was directly due to the presence of the bacteria themselves, but later researches have shown that such reactions are induced by the action of chemical poisons known as toxins which are produced by their respective bacteria whenever they find a suitable medium for their growth. For evident reasons, these interesting substances have attracted no little attention in efforts to properly analyze them.

That many of the true bacterial toxins are extremely powerful poisons there can be no doubt, especially when we consider the fact that some of them are approximately twenty times more potent than cobra venom and 200 times more so than aconitine, the acknowledged leader among drugs in this respect.

Toxins are not only elaborated when bacteria are growing immediately within the tissues, but they are also believed to be a product of saprophytic bacteria acting upon decomposing organic matter in the intestinal tract.

Considerable research has been attempted to definitely determine the composition of the complex toxin molecule, but as yet its chemical structure is almost entirely unknown, although there is good evidence to support the supposition that a toxin consists of two parts, a toxophore to which its toxic effect is due, and a haptophore which theoretically unites with its corresponding antitoxin.

In the main, this is nearly all we know about the bacterial toxins, and even so, these observations cannot be applied to the primary causative microorganism of tuberculosis, the *Bacillus tuberculosis*, for the cogent reason that this particular bacillus does not form toxins so far as we know. Many elaborate and skillfully contrived experiments intended to define this property of the tubercle bacillus have in all instances demonstrated a total absence of toxins. This fact, together with the further fact that tuberculous foci in the lungs, in many instances remain quiescent over long periods of latency and give no evidence of toxic disturbances in the body, justify the supposition that the tubercle

bacillus tends to localized processes only. Besides, the *Bacillus tuberculosis* is not saprophytic in the restricted use of the term, and neither is it a true pus-former.

The question of additional infection with symbiotic bacteria in pulmonary tuberculosis is no longer problematic or experimental. The widespread prevalence and almost universal infection by pus-formers is quite generally recognized and with this knowledge is gradually coming a true interpretation of the destructive processes in tuberculosis and their attending toxemias. Koch's bacillus alone is seldom very destructive of tissue until the biological balances are overthrown by the symbiotic factor which is added when the streptococcus and other pus-formers engraft themselves upon the latent, original primary tubercle. The truth is tuberculosis would be a comparatively mild disease were it not for the streptococcus-pneumococcus group of pyogenic microorganisms.

All of these facts are in harmony with the osmotic theory and tend to sustain the view that pulmonary tuberculosis originates primarily through a loss of natural immunity because of certain metabolic disturbances, the indication of which is the purpose of this paper.

The specific reactions produced in the body by infective viruses stimulate the organism to the formation of the so-called antibodies which confer an active immunity on the individuals against the particular antigen or virus which causes the reaction.

The antibodies now recognized are the antitoxins, bacteriolysins, opsonins, agglutinins, and precipitins; the last two, however, so far as known, have little immunizing action, although of considerable value for certain diagnostic purposes.

The exact nature of the antitoxins is, like that of the toxins, not very clearly defined. As the name implies, their immunizing value lies in their power to neutralize the poisonous properties of the toxins. Much of our knowledge of this complex reaction of the antitoxins upon the toxins is rather in a theoretical state of evolution, although the naure of the reaction, in so far as it relates to pure chemistry, has been quite clearly shown. Just how this reaction is brought about in the fluids of the body is not definitely known, and yet that such reactions are accountable for a considerable degree of our immunity to various diseases there can be but little doubt.

The antitoxins are believed by some investigators to be a product of certain chemical actions wherein the toxins are converted into the antitoxins or, as it were, into modified toxins. Again, there are reasons for believing that the antitoxins are, to some extent, at least, generated by the cellular elements of the tissues. It is also quite probable that defensive proteins are thrown out by the leucocytes which tend to neutralize the toxins and to destroy their bacterial sources. Those which destroy bacteria are called alexins and those which react against the toxins, as might be supposed, are antitoxins.

The antitoxins are highly specific and in consequence thereof, are effective only against that particular toxin which induces the primary reaction resulting in their generation.

As just intimated, the blood not only contains substances to neutralize the toxins, but also can destroy the bacteria themselves through the agency of bacteriolysins. These antibodies which occur in the blood in response to the reaction induced by the presence of an antigen or virus, owe their bactericidal action to their power of dissolving cellular elements in the presence of their complement (alexin) and their amboceptor or immune body. This in analogous to hemolysis in the Wassermann reaction, in which blood cells, the complement, and amboceptor form the hemolytic system. The absence of any one member of the system will prevent the process of hemolysis or bacteriolysis, as the case may be.

The last of the antibodies which may be of interest here are the opsonins. These chemical substances seem to play the very important part of preparing bacteria for assimilation by the leucocytes and in consequence thereof necessarily precede in the process of phagocytosis.

The phagocytes, as everyone knows, are white blood-cells, and possibly to some extent, endothelial cells, which gather at a point of infection and by means of their remarkable property of ameboid movement pass through the vessel wall and engulf bacteria by chemiotaxis to effect their removal; or as we have just observed, these cells may generate antitoxins and also complete the necessary system for bacteriolysis, the dissolution of bacteria.

From this rather rapid review, it is evident that a remarkable progress has been achieved in a general way in our studies on immunity, and yet it seems a little discouraging that more is not known about tuberculosis. Many thousands of experiments have been undertaken to help solve the riddle and we have tuberculin in twenty-two varieties at our disposal; nevertheless, one-seventh of all deaths are due to tuberculosis and this "Captain of the Men of Death" stalks on unavenged.

Continuing along the lines of the osmotic theory, suggested by the writer in a previous communication (MEDICAL RECORD, July 14, 1917), the following considerations are submitted in that they might throw some light on this maze of obscure phenomena in so far as pulmonary tuberculosis is concerned.

These observations lie in the broad biological base of the imperfectly understood metabolic phenomena depending on osmosis. Some of the observations necessary for a more perfect knowledge of the ultimate exchanges between the bodily fluids and tissue elements have given to experimentors results exceedingly difficult to interpret.

It is possible that some of the following considerations will disturb a few substantially rooted, preconceived notions, yet there is no legitimate reason why we should allow old traditional prejudices to neutralize the possibilities of progress and there should certainly be no exception in the present instance, where our common foe is defiant.

Undoubtedly, immunity to tuberculosis in many individuals is due to the simple fact that the tubercle bacillus does not find metabolic conditions in the body suitable to its particular needs.

Those conditions may either prevent the development of the bacillus or result in a destruction of the bacillus by virtue of certain properties residing in the tissues or fluids of the body; or they may neutralize the toxic products of symbiotic bacteria and destroy or prevent the growth of these. Finally,

as in the particular instance, of osmosis, all of those immunizing conditions may at once be brought to bear.

If the validity of the conception that the protective leucocytes, opsonins and other antibodies may not always find access to the tuberculous foci can be established, it is certainly a logical conclusion that the forces which may bring such indispensable immunizing agents to the issue should receive a more concerted attention.

Regarding the nature of a substance in solution, two theories, the hydrate theory and the dissociation theory, have been advanced. The former, not being accepted by the majority of chemists, will not be further detailed. The latter theory was developed from the study of the pressure exerted by substances in solution. This pressure is called osmotic pressure and may be illustrated experimentally as follows: If we carefully pour an aqueous solution of some salt or other crystalloidal substance upon the bottom of a vessel containing pure water, delivering it through a thistle tube so as not to mix the two, and then permit the vessel to remain at rest for a few hours, it will be discovered that the salt has diffused entirely throughout the water. This diffusion is due to the intrinsic activity of the molecules in solution. It can be further shown that if we separate the two liquids by a permeable or semipermeable membrane, diffusion will still occur, and it will be found that an excess of water has collected on the side of the salt solution. Formerly it was said that this salt attracted the water but the phenomenon is now expressed by saying that the salt in solution exerts an osmotic pressure.

Diffusion of this kind through a permeable membrane is called osmosis. Osmotic pressure is, for dilute solutions, the same as would be exerted by the solute if it existed as a gas of equal temperature and volume, and thus the ordinary gas laws of Boyle, Gay-Lussac, and Avogadro were found to hold for solutions. This is pertinent when we consider the analogy to osmosis in the diffusion of gases in the lungs.

Osmosis then may be defined as the tendency of fluids of different densities to diffuse through an intervening membrane, the intensity of the flow being greater from the thinner to the thicker fluid.

This is according to the law of Van't Hoff which may be expressed as follows: *"At constant temperature the osmotic pressure of dilute solution is proportional to the concentration (number of molecules) of the dissolved substance."*

Depending on variations in degree of density, osmosis in the body may be direct, when the intensity of the flow is in a normal direction between the capillaries and the tissues; or neutral when the fluids on either side of the capillary membrane have the same density; or indirect, when the intensity of the flow is in an abnormal direction between the capillaries and tissue elements.

These differences, however, are doubtless in many instances so slight that they may be determined only with considerable difficulty. The exceedingly fine balances maintained in the body preclude any possibility that these variations in the osmotic phenomena are present except in extremely small degrees. The slightest deviations from the normal may nevertheless neutralize and impair the intensity of the osmotic flow to such an extent that only an inadequate quantity of the protective leucocytes, together with the opsonins and other antibodies, may approach the entrenched bacteria.

It is well to remember that proteins, because of their large molecules, do not pass through permeable membranes by means of osmosis. The proteins are circulated in the blood as amino-acids which have smaller molecules and may readily pass through the capillary membranes by means of osmosis to the necessary nourishment of the tissues. For these same reasons the red cells do not migrate, but pass along through the ultimate and extremely minute capillaries to join similar capillaries of the veins. The classical exception to this rule of proteins is that of the leucocytes. These cells, because of their remarkable property of ameboid movement, are able progressively to contract their molecular size, as it were, and in this manner, more commonly known as diapedesis, succeed in passing through the capillary walls to the tissues beyond.

In the body we deal with aqueous solutions of various substances which are continually passing through intervening permeable membranes, such as the walls of the capillaries or of the alimentary tract, and the laws of osmosis are of extreme importance in explaining many of the complex processes relating to the formation of secretions, absorption of nutriment, and the protective or nutritive relations between the fluids of the body and the tissue elements.

Everywhere within the body there is a rich capillary network of vessels permeating every tissue. By means of osmosis the plasma (serum) which contains the protective and nutritive elements of the blood, consisting in the leucocytes, albumins and proteins in the form of amino-acids, sodium chloride, opsonins and other antibodies, is continually passing through minute membranes to bathe the tissues in the interstices of the capillaries.*

With the exception of the allied phenomenon of filtration, there is no other physical force as yet known, which will impel the bodily fluids through permeable membranes as a purely physiological entity; or, reversing the order, there is no other physiological agency, except filtration, whereby the bodily fluids may be made to pass through permeable membranes.

Filtration, unlike osmosis, is dependent on the pressure within the arterial system and is merely a process of forcing the fluids, as it were, through the membranes. Filtration is largely distributed as a process in organs more particularly engrossed with secretory functions, such as the kidneys or other abdominal organs.

That filtration could not possibly be allied with osmosis in the lungs is manifest by the extreme reduction in the pulmonary pressure, which is only one-eighth that of the aortic arterial pressure. Again, the extreme thinness and delicacy of the permeable capillary membranes in the lungs, being such as to bring the red-cells virtually in contact with the air in the infundibula, precludes even a possibility of a process of infiltration existing there. Besides, the lungs may be regarded as an osmotic

* "It is notorious in hospital practice how often the fatal event in arteriosclerosis, cirrhosis of the liver, etc., is a terminal acute tuberculosis."—OSLER.

membrane preeminently fitted for, and engaging exclusively with the phenomenon of diffusion and they are in no wise concerned with a physiological secretory function.

Unquestionably, when a moderate degree of mechanical stimulation is applied to the intervening permeable membrane, the intensity with which osmosis is accomplished may be to some extent augmented.

We probably have in this simple fact a solution of the perplexing problem of immunity throughout the muscular system and an explanation of the relative susceptibility of the more or less immobile apices of the lungs. With the exception perhaps of an occasional group of muscles, such as the psoas, all of the minute permeable membranes which form the capillaries of the muscles are under the influence of slight frictional movements which naturally encourage the passage of leucocytes, opsonins, and other immunizing bodies through such membranes as occasions for defensive measures arise.

However, if a focal tuberculosis develops, undue motion merely disseminates the infection.

In the lungs, three distinct regions may be recognized according to their degrees of mobility. The apical, or relatively immobile; the middle, or moderately mobile; and the lower, or actively mobile in consequence of being nearer the diaphragm. It would seem that such conditions should favor the apical region as the first to manifest primary tubercles. Whether the eparterial variations at the hilus influence the right or left apex in degree of frequency it is impossible to say.

The insensible variations in osmosis are more conspicuous in the grosser evidences of a disturbed metabolic balance observed in the processes of growth, reproduction, assimilation, and repair with which osmosis is inseparably concerned.

In the particular instance of growth, it is not infrequently observed that those individuals who manifest a disturbed osmosis and rapidly acquire a tall and slender growth throughout adolescence, are more particularly susceptible to subsequent tuberculous involvement.

In the instance of reproduction, all of us are familiar with the pathetic circumstances of the pregnant tuberculous woman who evidences some apparent recession in the tuberculous symptoms during gestation, only to succumb the more rapidly after the osmotic activities of reproduction have subsided.

In the instance of assimilation, the problems of infant feeding naturally come to mind. Efforts to support metabolism by means of the bovine milk molecule which differs in many vital respects from the human milk molecule and among other things does not osmose readily in the process of absorption from the intestinal canal, are frequently attended with grave consequences.

In the instance of repair, when the normal osmotic activity has been disturbed, possibly for months or even years all of the dependent physiological processes become impaired to a corresponding degree. Digestion, absorption, secretion, the protective and nutritive functions of the blood or lymph, and many other vital processes become more or less impaired. The balance between repair and elimination fails to be maintained, while the increasing burden placed upon the already subnormal physiological systems becomes greater than they are capable of sustaining. Eventually, a subtle condition of hypotonicity is introduced and the individual susceptibility to infectious bacteria increases. The affected individual is conscious of some vague, slowly progressing condition gradually undermining him, although he is at a loss to localize any particular group of symptoms. He tires easily and there is a general feeling of languor and lassitude. Sooner or later symptoms manifest themselves in the lungs and incipient tuberculosis is in evidence.

The widespread and almost universal distribution of the tubercle bacilli justifies the supposition that we are frequently taking them into our organisms either through the respired air or in our food, and doubtless from early infancy, many of the bacilli invade our bodies.

A normal breast fed infant, let us say, receives a few of the bacilli which find their way to the parenchyma of the lungs or other organs, and being intent upon their own propagation, immediately commence to multiply.

Assuming the osmotic activity to be direct and normal throughout the body, an adequate quantity of opsonins will pass the capillary membranes to the vicinity of the bacilli. Simultaneously, the leucocytes in sufficient numbers pass through the capillary walls, and the attack on the invading bacteria is merely a process in bacteriolysis and perfectly analogous to hemolysis; the bacteria (cells) being dissolved by the complement and amboceptor which complete the bacteriolytic system; or the leucocytes may engulf the bacteria by the aid of opsonins and promptly effect their removal. Our infant subject may then be said to possess a natural immunity.

That these protective or immunizing forces are in almost constant engagement with bacterial invaders somewhere within the body is quite probable.

Unfortunately, the artificial methods of infant feeding which are merely intended as strategic and imperfect substitutes in the occasional emergency when it becomes expedient to remove the infant from the breast, have led to a neglect of the possible dangers in such practices and it not infrequently happens that cow's milk is actually preferred to the provision made by nature. Especially under such circumstances the metabolic balances are not infrequently disturbed and the long chain of phenomena in the nutritive processes of the infant becomes seriously impaired and an imperfect or neutral osmosis is eventually induced while the natural immunity gradually becomes transformed into an acquired susceptibility. The bacilli which then invade the body are destroyed with considerable difficulty or not at all.

The seriously impaired osmotic activity is perhaps augmented to a sufficient degree by mechanical stimulation of the permeable membranes throughout the muscular system to maintain an apparently normal resistance in the muscles.

In the liver or other abdominal organs, the neutral osmotic flow is no longer an immunizing factor, and yet the allied phenomenon of filtration is sufficiently active to impel the leucocytes and other immunizing bodies through the capillary walls by means of arterial pressure, and in consequence

thereof an apparently normal immunity of almost all of the abdominal organs is maintained.

However this may be, there are certainly no allied forces in the lungs to assist the inefficient neutralized osmotic activity. Possibly in the regions of greatest mobility, the middle and lower, the slight mechanical stimulation received from respiratory movements may temporarily assist the immunizing bodies through the permeable membranes and a partial immunity may be for a time continued.

In the immobile apices and bronchial lymph glands, exiled entirely to a dependency upon osmosis for their immunity, the conditions would seem to contribute to the security and propagation of the bacilli and consequent primary tubercle formation.

The question of the more frequent involvement of the bronchial lymph glands in childhood is one of considerable difficulty to satisfactorily explain, and yet it is doubtless true that the lymphatics distributed along the pulmonary circulation are quite entirely dependent upon osmosis for their immunity.

The presence of the tubercle bacilli at various foci in the lungs, and in the absence of sufficient immunizing bodies, stimulate a local cellular activity until the bacilli are entirely sequestered by encapsulation in fibrous tubercles. This provision of nature would seem to adequately meet many protective requirements inasmuch as the tubercle bacilli are decidedly aërobic and non-motile. Their requirement for oxygen in fact is so great that experimental inoculation of artificial culture media is attended with reverses unless the inoculation is very lightly and superficially made on the surface of the medium.

Encapsulation then, depriving the bacilli of a necessary requirement for their growth, places them in a relatively harmless status; yet, the primary tubercles thus formed are a source of constant attraction for the many forms of pyogenic bacteria and unless our infant subject should acquire a more normal osmotic activity, these symbiotic bacteria readily engraft themselves upon the primary tubercle and an inevitable toxemia, with other tuberculous signs of activity, is introduced.

With the return of a normal immunizing osmotic activity the possibilities of secondary infection are negative, and although the primary tubercles originating in the infant continue throughout life as a constant source of attraction for pyogenic bacteria, of which there are so many varieties, as long as the normal direct osmotic activity remains unimpaired, the immunizing elements in the circulation will constantly and efficiently defend our organisms.

That the leucocytes readily come under the control of Van't Hoff's law of osmosis is evident from the remarkable provision made by nature in maintaining the erythrocytes in an axial stream while the leucocytes arrange themselves closely along the capillary wall when they gather in large numbers at a point of severe inflammation. If they were uniformly distributed throughout the volume of blood in the vessel they would probably modify the osmotic pressure while their necessary migration would be interfered with according to the law that the osmotic pressure is proportional to the number of molecules concentrated or uniformly distributed in the solution.

The improvement of an impaired osmosis in the body should be followed by a more normal physiological activity in the functional characteristics of many vital processes.

The exact origin of the leucocytes is still under consideration, yet there can be but little doubt that whenever the physiological units from which they may be derived are functionating normally, they are produced more efficiently than could be supposed if such physiological units were in a state of hypotonicity because of a prolonged impairment in osmotic activity.

Tuberculous individuals with a leucopenia, or very low leucocyte count, are invariably known to have a relatively bad prognosis.

That the improvement which is frequently observed after simple incision and drainage in abdominal tuberculosis might be due to the removal of an abnormal source of osmotic pressure in the pathological fluid, is a possibility.

Although some of the complex physiological processes which seem to enter into the phenomena of immunity are somewhat imperfectly understood, it is undoubtedly true that immunity in pulmonary tuberculosis, by whatsoever means acquired, will pass in through the gateways of osmosis.

Much remains to be achieved; nevertheless, it is possible that enough has already been revealed to direct the way to that substantial factor which will emancipate the noble organs of respiration and inevitably conquer the dark forces leagued against them.

THE MANAGEMENT OF DECUBITUS, A SYSTEM IN USE AT KINGS COUNTY HOSPITAL.*

By WILLIAM BROWNING, M.D.,

BROOKLYN, NEW YORK.

THE successful management of bedsores is an old criterion of good nursing. This condition has so oft been anathematized that its recurrence but proves its disreputable character. Of course such a condition should never be allowed to develop. Nevertheless, anyone with accurate olfaction cannot frequent hospitals without now and then detecting the tell-tale effluvium.

At the Kings County Hospital, the final refuge for all the derelicts of some two million people, wretched cases of this kind have from time to time to be admitted. And where, as in the neurological service, there is commonly an underlying defective innervation of the affected parts, the problem of care and relief is a most serious one. It consequently became necessary to work out a more advantageous plan than those long in vogue. This was done partly on the basis of past methods for the treatment of this condition, and partly by the devising of additional means. The system now followed can best be described as a connected whole. Whether all the principles involved are or are not applied elsewhere matters little, while exceedingly laborious in the carrying-out, they yield results that it has not been possible to secure otherwise.

Certain generally understood preliminaries are a

*From the Neurological Department of Kings County Hospital.

necessity for success, and can be briefly summarized:

1. A hospital personnel that can be absolutely depended upon. Without this nothing is to be expected. And a sniff of the atmosphere anywhere about the patient's bed gives a prompt control of the efficiency obtained.

Suggestion of a Decubitus Division.—Where there is constant work of this kind—and one case may be enough—it would be an excellent innovation to have it handled in a special or separate section, thus insuring attendance by the same physicians and accustomed nurses. The duty is so distinct that it is not likely to be well carried out by any other arrangement. And the welfare both of the sufferers and of other patients would thus be greatly conserved.

2. Cleanliness. As many of these involvements are of parts about the hips and pelvis, and incontinence (bowel and bladder) frequently adds its burdens and dangers, the securing of cleanliness becomes a most trying part of the task. Any discharge (whether the patient be conscious of it or not) must be promptly removed.

3. Change of the patient's position. The areas of skin bearing the body weight must be relieved with a frequency dependent somewhat upon its reactivity. Often every half-hour day and night is the longest permissible interval. And where the skin shows engorgement and lividity the change may need to be made even more frequently. Sometimes this can be done by turning the patient from side to side; occasionally the back can be used briefly or the prone position. Again cushion-rings and other substitute points of rest can be arranged. And where the patient's general status permits, some recourse to the sitting position is very advantageous.

Resort to air- and water-beds may aid a little in some cases, although the liability of chilling is considerable with either. In summer this is less; and even in winter, if the warmth of the water can be surely preserved, it may be permissible; or a thin intervening pad may suffice.

In general, of course, the prevailing posture must be such as to permit the gravity discharge of secretions from any ulceration.

4. For local preventive treatment a most rational and useful agent is the alternate application of heat and cold described by Weir-Mitchell in his work on nerve-injuries. One advantage of this is its availability practically everywhere. Especially in the common cases where trophism is much at fault this form of stimulus is doubly necessary. It can be repeated as many times a day as found advantageous. In general, its purpose is to improve local circulation, stimulate trophism, and favor cleanliness.

The methods so far outlined usually suffice for the prevention of even threatening bedsores. They are consequently available for both prevention and cure. But where the ulcerative, sloughing, gangrenous, pus-forming, and burrowing stage has once developed, these means must be supplemented. And we now come to the only part of the scheme, if any, that has an element of novelty.

The usual routine of simply adjusting a pad of oakum or a dressing of any convenient antiseptic finds in practice little to commend it. The most thus accomplished is a partial absorption of accumulating filth.

What is needed is an application that penetrates, disinfects, deodorizes, checks secretion, and, if possible, has some constricting quality. Bichloride of mercury does not penetrate. Carbolic acid and its kind may sear the surface, but hardly get further, and in these conditions are specially liable to induce carbolic gangrene.

There is one agent, however, that can favorably affect the tissues, and accomplish all these desirable effects. That is formalin (formaldehyde), as shown by its application in histology, but used of course in proper dilution. The peculiar qualities of this agent and their adaptability to the purposes in question need no discussion. A half per cent solution of the usual 40 per cent standard strength serves these ends admirably, and with care causes no undesirable irritation.

A convenient way to meet the various indications each time is to cleanse the ulcer and all its ramifications with plain boiled water as warm as can be handled. Then finish with the cold formaldehyde dilution, getting it well into each crypt and sinus. This includes automatically the stimulating effect of alternating temperatures.

To avoid the exsiccating action of the solution on the user's hands it might doubtless be applied by means of swabs or under the protection of rubber gloves. With us the custom is to make the application with a syringe, this method has the advantage of facilitating its introduction into all pockets and covered tracts and its contact with the exposed surfaces.

Finally it is necessary to have a dressing material that in the intervals of cleansing keeps up the action so far as practicable. For this purpose the subiodide (oxyiodide) of bismuth has been found very satisfactory. It is dusted on in sufficient quantity to make a protective absorbent and antiseptic layer everywhere over the area.

This whole dressing must be repeated as often as requisite for cleanliness, at the start several times in the 24 hours, and thereafter twice or thrice a day is a minimum. When the raw surface becomes dry and clean crusts form, they may be left undisturbed to facilitate cicatrization.

The progress in a given case is naturally influenced by the general condition of the patient. In, for example, neglected cases of multiple neuritis in middle life, as the general disorder responds to treatment, we can see a marked acceleration in the local response as well; even desperate cases of this sort may recover and leave the hospital with only a well-scarred back as a residuum. If, on the other hand, the decubitus is an accompaniment of some destructive central lesion, a slower course is to be expected.

This system has been in use in this service for several years now, and has given such satisfactory results that it can be commended. So far as local treatment can avail, this plan fills the bill. And it has the advantage of being simple in theory and application. Like any useful method for this condition, however, it entails an unavoidable amount of trouble.

54 Lefferts Place.

RECENT ADVANCE IN THE TREATMENT OF KIDNEY DISEASE.*

By JOHN R. WILLIAMS, M.D.,

ROCHESTER, N. Y.

In the year 1827 Richard Bright, working in Guy's Hospital, London, published his "Reports of Medical Cases," in which he described for the first time in the history of medicine nephritis as we now understand it. So accurate and comprehensive were his powers of observation and so clear and definite were his descriptions of this disease that he left but little for succeeding clinicians to unfold. Indeed, but very little progress had since then been made in the study and treatment of kidney disease until the recent advent of the science of biological chemistry in this field within the past few years.

In this brief paper we shall consider only the chronic interstitial type of the disease, because it is the most common and least understood. It develops under the eye of the general practitioner in the most insidious manner and rarely comes to the notice of the hospital clinician until it is well established. It is well, therefore, for the general practitioner to have in mind certain facts and simple methods of investigation which will assist him in its study and treatment.

The etiology of the disease, while indefinite and obscure, is most important. It is remarkable how frequently this disease runs in families. In more than half the cases which the writer sees there is a paternal or maternal history of arterial degeneration. We cannot say that the disease is inherited, but we ought to assume that the liability to it is transmitted from one generation to another. Kidney degeneration when it thus appears in families usually comes in about the same decades. One therefore should not only take careful family histories but he should watch out for signs of degeneration in the members of such families as they approach this decade characterized by the appearance of kidney disease.

Kidney disease and arterial diseases are nearly always found in association with focal infection in the head, chiefly the teeth and tonsils. Rarely does one see this type of disease in an individual in the absence of focal infection; on the other hand, persistent focal infection is nearly always accompanied by renal irritation. Therefore while we cannot say that a persistent low-grade infection in the mouth is the direct causal agent of arterial and kidney degeneration, we are warranted in viewing it with suspicion. Out of 234 such cases which the writer has seen within the past year or two, in only twelve instances was there an absence of obvious mouth infection. In the treatment of kidney disease, we find further proof that persistent low-grade infection is a contributing causal agent, for when it is removed one often notes an arrest or amelioration of the disease.

Methods of Study and Their Relative Value.—The history of the patient is worthy of careful study. Occipital headache, dizzy spells, gastric symptoms, weakness, shortness of breath, cough, and, most important, a night polyuria are all suggestive. The value of the family history has already been alluded to. An overacting heart and high blood pressure are the most striking points on physical examination. The simple tests of the urine for albumin are of very little value. Taking the specific gravity of a single specimen is of even less importance. Neither of these tests gives reliable information as to the presence of the disease or of its seriousness. Accurately saving the urine for twenty-four hours in periods of twelve hours representing the day and night, measuring these and determining the specific gravity is quite valuable. A patient who passes from 20 to 30 ounces of urine or more during the night, unless this can otherwise be explained, is quite likely to have a sclerotic kidney. Accurately saving the urine in two-hour periods during the day from 7 A.M. to 9 P.M. and from 9 P.M. to 7 the next morning, measuring this and taking the specific gravity of each sample will give information of the greatest value. A normal person will eliminate amounts of urine varying very greatly in volume during the day, depending entirely on the amount of fluid taken. Moreover, it will be eliminated promptly after it is ingested. During the night period of ten hours but little, if any, more urine will be eliminated than during any of the two hours of the day. The specific gravity of the normal urine will also vary widely in the sample from 1006 to 1025 or more. There is a similar response to meals. The sclerotic kidney in proportion as it is diseased will eliminate practically the same amount of water every two hours irrespective of what may be ingested, and during the night period the volume may equal or exceed the total excretion of the day. This tendency to uniformity in amounts of urine and in specific gravity and the failure or delay in responding to the ingestion of food is known as fixation by the kidney. It means that the kidney is already working under high pressure and is unable to respond promptly to the additional work thrust upon it by the ingestion of food and drink. In the scientific laboratory we investigate the excretion of nitrogen and salt in the same way and gain further valuable information. The first part of this test can easily be carried out by the general practitioner and is well worth the trouble and labor it imposes.

The ordinary urea test by the hypobromite method is valueless. Of the many functional kidney tests which have been suggested, the phthalein test is by far the most useful. Any practitioner at a very small expense and with no laboratory training can readily do this. In conjunction with other methods of study, it usually yields very valuable information. When kidney degeneration becomes severe, phthalein elimination declines often to the vanishing point, but not always. When taken in conjunction with the two-hour renal test, the blood pressure and heart examination, and also the examination of the eye grounds, the general practitioner can form a very reliable estimate of the seriousness of his case and the utility or futility of his treatment.

A brief description of the more refined and technical methods of study which necessitate a well-equipped metabolic hospital unit, including both chemical laboratories and special diet kitchens, may be of interest. For the accurate study of this disease, a patient must be placed under conditions

*Read before the Lake Keuka Medical Association July 5, 1917.

where his food can be accurately prepared and served, and where all of his excretions may be saved. Under these conditions, certain blood and urine studies yield information of value which is otherwise unattainable. Under these conditions the study of that portion of the nitrogen in the blood which exists in the form of uric acid, urea, and creatinin is both fascinating and useful. Kidney disease is always accompanied by a disturbance of protein metabolism. Consequently there is usually defective nitrogen elimination with retention. The problem is a most intricate one and too complex for simple presentation. Further, there is no unanimity of opinion as to the best methods of study or as to the significance of the data thus afforded. Urea in the blood is the result of food metabolism, creatinin is the result of cell metabolism, never of food metabolism. The normal blood contains from 1 to 2.5 mg. creatinin per 100 c.c. If creatinin is present in excess of 5 mg. per 100 c.c. of blood, the prognosis of the case according to Chace is very serious, death is likely to ensue within a year. The writer's experience tends to confirm this observation.

There is a definite relation between the concentration of urea in the blood and its elimination by the kidneys into the urine. This was worked out by Ambard and amplified and improved by McClean and is known as the coefficient of urea excretion. With an increasing kidney deficiency this coefficient rises, when the kidneys become more efficient it falls. When the kidneys are overactive from irritation, as in fever and in the early stage of kidney disease, it may be lower than normal, but when the kidneys begin to play out, it rises much above normal. It is perhaps the best method of measuring the progress of kidney disease. By it, kidney changes can be detected earlier than by any other method.

Advanced nephritis is attended by acidosis, both local and general. Howland has shown that the general acidosis of kidney disease is due to the retention of phosphates. His method of study has not yet been published but the fact is of clinical value. There is probably also an acidosis in the kidney but this is not demonstrable. Nephritics usually show a deficiency of calcium in the blood; and since calcium is necessary for the metabolism of iron, the iron content of the blood is also low, with a resulting anema. Calcium also favors the elimination of the phosphates, therefore it is one of the most valuable remedies in the treatment of the disease.

A few words as to treatment. Christian[1, 2] has shown, and the writer's own experience confirms this, that diuretics are practically worthless. If a patient is dyspneic and edematous, it is quite likely that he has a disturbance of salt metabolism. The Karell diet in such cases works marvels. The patient is given no other food than one quart of milk and one pint of water daily for a week or perhaps two weeks. Edema usually quickly disappears. Six to eight ounces of lime water or better still one dram of calcium lactate and fifteen grains of Blaud's mass are given daily in divided doses. Later starchy foods and vegetables rich in calcium and iron are added. Protein food is given according to the ability of the body to take care of it. It is the writer's plan to put these cases on low diets, cautiously building them up as above suggested. At the same time a record is kept of their muscular vigor by means of a dynamometer. As a result of the studies which have thus far been made, the writer feels warranted in saying that a patient will gain in muscular vigor on a diet which his body can care for even though it be much below his normal needs, and he will lose in muscular tone if he is fed ever so cautiously beyond his metabolic limitations.

The writer has seen no good from the persistent purging with salts or the use of hot packs; and drugging with diuretics is to be condemned. The greatest care should be taken to get rid of all infection. Rest in bed is valuable.

To summarize the foregoing. Kidney disease is probably a constitutional disease with kidney manifestations. In many cases the liability to it is transmitted from parent to offspring.

Focal infection is commonly associated with nephritis and may bear a causal relation to it.

Every adult over forty with a family history of kidney disease should get rid of all such infection and should be examined at least three times a year for evidences of beginning kidney degeneration.

The best urine test for the general practitioner is the two hour renal test. Tests for albumin and casts are much less valuable.

The phthalein test is extremely valuable.

Blood studies for non-protein nitrogen, urea, creatinin, and the determination of the Ambard-McClean coefficient are very valuable but must be done in a well equipped hospital. The Karrell diet is the best treatment for advanced cases with edema and dyspnea.

Death is caused by acidosis, probably due to the retention of phosphates.

Calcium and iron both favor the elimination of phosphates and are therefore the best medicines for the disease. Packs, purgings, and diuretics are practically worthless.

The following cases illustrates the value of these methods.

Case 1970. Male age 28 years. Albumin found in urine at insurance examination three years before and has been present in varying amounts on numerous examinations since. Systolic blood pressure varies from 120 to 140 mm., diastolic pressure 80 to 90 mm. Recently has had slight dizzy spells and nausea. History of severe tonsillar and middle ear disease in 1912. Tonsils partly removed. Part of left tonsil persists and shows areas of degeneration and infection.

Two-Hour Renal Test.

Diet: Carbohydrate, 148 grams; protein, 80 grams; fat, 115 grams; calories, 1930. Salt, 7 grams. Total volume fluid intake, 1490 c.c.

Hours	Fluid Intake, c.c.	Urine, c.c.	Specific Gravity	Nitrogen		Salt	
				Grams	Per Cent.	Grams	Per Cent.

Totals...	1490	1349	.....	29 76	.....	9 82	.

Urine. Specific gravity varies from 1020 to 1030. Patient passes from 350 to 550 c.c. during night. Small

amount of albumin present, also many hyalin and granular casts. Phthalein output in two hours 49 per cent. Urea in blood 40.6 mg. per 100 c.c. blood. Creatinin 1.2 mg. per 100 c.c. blood. Ambard-McClean coefficient 0.089.

Comment. The excretion of water during the day from noon on is quite constant in amount when compared with the intake. This suggests that the kidneys are working under pressure, have not much reserve, and tend to tire out during the day. This is known as fixation. The same condition will be observed in the percentage of solids present as is revealed by the specific gravity which is quite constant during the latter half of the day. Nitrogen metabolism is on a very high plane, the patient having lived on a very high protein diet preceding the test. It will be noted that there is not much fluctuation in either the amounts or percentage of concentration of either nitrogen or salt after the noon hour, indicating fixation of these elements to a considerable degree.

The foregoing examination has the following significance. The patient, while young and vigorous and as yet not showing any very appreciable renal symptoms, is passing to the stage where indications of disturbed kidney function are becoming evident which probably will soon give rise to noticeable clinical symptoms. The phthalein is slightly below normal. The blood urea and creatinin are practically normal, as is also the Ambard-McClean coefficient. The two hour renal test would indicate that the patient's diet is too rich in nitrogen and that the kidneys have not the normal reserve. With proper care, the prognosis in this case is good. The diseased tonsil should be removed.

Case 1875. Male age 63 years. Complains of gastro-intestinal distress, dyspnea, weakness, and prostatic obstruction. Systolic blood pressure at beginning of observations was 180 mm., diastolic pressure 100 mm. After several months of study and treatment, systolic blood pressure varied from 120 to 140 mm. and the diastolic from 80 to 90 mm.

Urine examination showed a small amount of albumin and much pus, specific gravity 1011. Several two-hour phthalein tests in a period of six months gave readings of from 2 to 5 per cent. Several total non-protein nitrogen determinations of the blood made at intervals of about one week were as follows: 178 mg., per 100 c.c. blood, 206 mg., 194 mg., 142 mg., 156 mg., 198 mg. and 122 mg. The normal is rarely above 50 mg. Creatinin determinations were as follows: 9.4 mg. per 100 c.c. blood, 8.0 mg., 10.0 mg. According to Meyer and Chace above 5 mg. means a fatal issue. Urea in blood was 184 mg. per 100 c.c. blood. Urea in twenty-four hour urine on this day was 16.9 mg., giving an Ambard coefficient unusually low of 0.56.

Because the patient had to be catheterized, it was impossible to make a two-hour renal test, therefore the four-hour catheterized specimens were examined and are as follows:

Four-Hour Renal Test.

Diet: Carbohydrate, 111 grams; protein, 26 grams; fat, 37 grams; calories, 962. Total volume fluid intake, 1020 c.c.

Hours	Fluid Intake, c.c.	Urine, c.c.	Specific Gravity	Nitrogen		Salt	
				Grams	Per Cent	Grams	Per Cent

Totals...	1020	1215	.....	3.79	.....	3.66	.....

Comment. This patient presents the clinical bedside picture of an individual extremely ill with nephritis. The serious weakness, difficult breathing, and feeling of oppression caused by an equality between the lesser and greater circulations, the urinous odor to the breath, all find adequate explanation in the laboratory examinations of the case. The prognosis in this case is very grave, although the patient has shown very marked improvement on the treatment outlined in this paper and is now attending to his business.

It is evident to one who has an opportunity of closely studying many cases of arterial hypertension that a very considerable number of them are caused by some other agency than disturbed renal function. The following case is illustrative of a number seen by the writer.

Case 1853. Female age 56 years, married. Complains of rapid heart action, swelling of ankles, pain in shoulders and back.

Important points from case history. Father and one brother died of gangrene of feet; personal history, negative.

Physical examination; heart, soft mitral bruit, compensated; toes cyanosed; ankles slightly puffed out but no edema; no evident thyroid disturbance. Blood pressure, several determinations over a period of months, systolic ranged from 190 to 225 mm., diastolic from 100 to 120 mm. Urine, specific gravity fluctuates from 1012 to 1028, amount from 900 to 1900 c.c. Trace of albumin commonly present, but no casts or renal elements. Excretion of chlorides normal on test diets for two weeks.

Blood urea 40 mg. per 100 c.c. blood, creatinin 1 mg. per 100 c.c. blood, Ambard-McClean coefficient 0.103. The two-hour renal test was as follows:

Two-Hour Renal Test.

Diet: Carbohydrate, 120 grams; protein, 47 grams; fat, 76 grams; calories, 1345. Salt, 10 grams. Total volume fluid intake, 1350 c.c.

Comment. In the foregoing test, the only datum suggesting a renal disturbance is the night polyuria. All the other data point to a normal kidney function. A renal lesion producing a systolic blood pressure of 200 or more would be likely to produce some striking evidence of disturbed kidney activity which is absent here. Indeed, aside from the night polyuria, this might be taken as an example of normal renal function.

The following case is a good example of the final stage of the disease. It terminated fatally after being under observation for two months.

Case 1924. Male age 43 years. Systolic blood pressure ranged from 190 to 230 mm., diastolic pressure from 160 to 190 mm. Phthalein output in two hours 14 per cent. Creatinin observations made at intervals of a week or less were as follows: 6.4 mg. per 100 c.c. blood, 5.3 mg., 6.6 mg., 8.7 mg., 12.1 mg., 16.1 mg. 24 hours before death. The blood urea over the same time was as follows: 74.9 mg. per 100 c.c., 98.0 mg., 252 mg., 418 mg. just before death. The Ambard coefficients in the last ten days were 0.214 and 0.750. The patient was in deep uremic coma for 72 hours preceding death and the foregoing figures represent the extreme failure of kidney function.

Two-Hour Renal Test.

Diet: Carbohydrate, 64 grams; protein, 32 grams; fat, 32 grams; calories, 640. Total volume fluid intake, 1740 c.c.

Totals...	1740	1299	.....	11.17	.....	1.93	.....

The above two-hour renal test was made two months before death. It showed a moderate fixation of water excretion, a well marked fixation of specific gravity, and nitrogen excretion. Salt metabolism was on a very low plane and undoubtedly explained the severe edema from which the patient suffered.

Of the two methods of kidney investigation, it would appear to the writer that the blood chemical studies furnish the most reliable evidence of the condition of the patient and afford a better prognostic guide than does the two hour renal test. The blood chemical methods are too complex and beyond the laboratory means of the general practitioner and indeed the majority of hospitals. The two hour renal test on the contrary is much simpler. Important and valuable parts of it can be done by the practitioner without any technical training or laboratory experience. Merely accurately measuring the urine excretion and determining its specific gravity every two hours during the day and estimating the night urine are extremely valuable guides in diagnosis, treatment, and prognosis. The phthalein test is very simple and equally valuable.

ELECTRICITY THEN AND NOW.*

By WILLARD TRAVELL, M.D.,
NEW YORK.

In undertaking a consideration of the influence of this Association in the field of electrotherapeutics since its organization in 1891, I was prompted to review its work as shown in its published transactions. Such a review awakens a realization of work done on a very large scale—papers presented to the number of many hundreds dealing with the use of electricity in every conceivable ailment of the human body, committee reports exhaustive in scope and detailed study, and discussion of both papers and committee reports almost endless in volume and of great interest.

Electrotherapeutic work of recent years has been very different in character from that of the early nineties. Before that time there had been no united effort to study its problems, much crude and unsatisfactory work was being done, and the merit of electricity in medical practice was justly questioned by the profession at large. They were true pioneers who in 1891 organized with the avowed purpose of placing electrotherapeutics on a plane with surgery and drugs.

To appreciate the changes since that time it is necessary to remember that commercial electricity with modern motors was not then available and the only apparatus in common use was the galvanic battery of from two to sixty cells, the faradic coil of small size, and the static machine of two, and at most four, revolving plates. A very few had a crude form of sinusoidal apparatus, the electric light had not come into use, there was no electric vibration, and the *x*-ray and radium had not been discovered. The static modalities were sparks, roller sparks, and the static breeze; there seemed no easy way of determining polarity, and as to whether static electricity had any value at all other than psychical was a matter of serious debate.

One of our most esteemed workers said in 1895: "By static electricity I have never yet succeeded in even temporarily relieving a case of sciatica of any kind from any cause, known or unknown." How different from the confident assertion by an equally esteemed worker a dozen years later who said in speaking of the value of static electricity, "I have yet to see the case of simple acute sciatica which I cannot relieve in ten days." The difference lay partly in the fact that in the meantime the static machine had become an instrument of vastly greater power with corresponding increase in efficacy, and partly in the discovery by one of our members and the prompt development of its therapeutic action by another, of that most valuable of all the static modalities, the static wave current.

Galvanism was the favored current in all forms of treatment. It is a fact that then as now this was used generally to stimulate the circulation, improve nutrition, cause absorption of exudates, cause ionic penetration of medicinal substances, and destroy tissue directly or by metallic ionization; but so much of the proceedings of the early years of the Association were devoted to the treatment of genitourinary diseases in men and women that the first impression made on an impartial observer must have been that electrotherapeutists were a group of enthusiasts who were trying to convince themselves that galvanism and faradism constituted a near-cure-all for all such diseases.

Concentration of attention upon gynecological conditions was doubtless due to the unsatisfactory results of the surgery of that period, but to us of today feelings of wonder are aroused at the daring of the electrotherapeutist in employing a technique which would seem often to have carried more danger of disaster than promise of relief. Practically all pelvic disturbances in women were treated by the use of an intrauterine electrode, while the accepted method of treatment for uterine fibroids was by the insertion into them of long needles per rectum, vagina, or cervical canal, for galvanic ionization. Hundreds of cases were reported with claims of a very large percentage of cures. The prostate was treated with equal daring. The galvanocautery here ruled as a favorite for a certain period and aroused a pitch of enthusiasm equal to galvanopuncture. It was declared that "the galvanocautery cures all cases of hypertrophied prostate; it is harmless even at the age of eighty; there are no bad postoperative effects; the operation is painless, the results permanent, and no case has been known to recur."

Gradually the influence of frank discussion and of more carefully compiled and later case reports was felt, and a more rational and conservative opinion prevailed. In 1900 it was definitely acknowledged that electropuncture seldom cured fibroids, that it merely reduced their size, and that electricity for fibroids should be used only to control hemorrhage. For treatment of this condition an improved surgery then held sway until displaced very recently

*Read as the Presidential Address at the Twenty-seventh annual meeting of the American Electrotherapeutic Association under the title "The Influence of the American Electrotherapeutic Association Upon Electrotherapeutic Practice."

by the *x*-ray with its proven curative power and manifest superiority.

The introduction of commercial electricity provided a constant current unlimited in quantity and easy of control, but recognition of its limitations and dangers coupled with the development of other apparatus and other methods of procedure diminished the popularity of this current, so that it no longer remained the modality of first choice in the hands of most electrotherapeutists.

For our share of the credit for progress in the whole field of electrotherapeutics, I know not whether to give more credit to the established habit of free discussion of papers, or to the work of our various committees which in the course of these many years have spurred the manufacturers on to the production of more efficient types of apparatus, and have worked unceasingly in the study of the various electrical modalities, and to determine the correct procedure for their use.

It is many years since the requisites for an electrotherapeutist were a galvanic battery, a faradic coil, and a feeble static machine. To the experienced worker, the varieties of electrical force now at our command offer free choice as to method of treatment; to the beginner they mean confusion and uncertainty as to what to do in any given case; while to the uninitiated physician or surgeon the very names of our most valued agencies mean nothing at all and the whole subject is to them a closed book. To enumerate some but by no means all of the modalities in common use today: the static machine offers the static induced current, the wave current, vacuum tube currents, sparks, sputtering and blue pencil brush discharges, the d'Arsonval current, resonator effleuves and sparks, and desiccation; the various coils and transformers provide diathermy, autocondensation, vacuum tube discharges, effleuves, sparks, and fulguration; the constant current is always available in any quantity and under perfect control; there are many varieties of sinusoidal apparatus; light, either as white light, blue light, or ultra-violet is highly valued; hot air, water at varying temperatures, and vibration are within our province; while the *x*-ray and radium are no longer reserved for diagnostic work but have come into play as most valued therapeutic agents.

Not only are there so many modalities in use, but it is a fact that in the treatment of similar conditions individual workers follow lines of treatment at such apparent variance with each other that a casual study of our methods adds to the confusion of the inquiring mind. For the good of all I enter a plea that our efforts be continually exerted toward establishing the simplest possible technique capable of producing the desired result.

The maxim has been propounded by one of our number that fundamentally the physiological effects of all electrical modalities are either thermic, mechanical, or electrolytic. The mechanical effects are chiefly in the production of tissue and muscular contraction, and are readily recognized. *Heat* is produced by all the various modalities; it is the ultimate result of transformation of energy in the tissues, and it is in direct proportion to current strength and resistance. The constant current causes some definite and unique local effects, but except for very local effects in the immediate field of application of the electrode, I believe the terms electrolysis and ionization as applied to the working of this current have a theoretical and vague meaning, and that we should think of the action of the constant current in the deeper tissues in terms of simple heat units. High frequency and particularly the transformer currents create heat through and through the body to any desired degree. The *x*-ray becomes more and more popular in the treatment of many conditions. In larger doses than those which produce stimulation, the effects are inhibitory, interfering with germ development, lessening protoplasmic activity, diminishing secretion, promoting retrograde changes in fibrous and malignant tissue; but it is recognized that in small doses its effects are very stimulating, and it is a question if in the case of the *x*-ray also, the final inhibitory effects of large doses may not be analogous to those of heat applied in degree more than stimulating, yet short of immediate destruction of tissue.

Moderate heat gives renewed vitality to protoplasmic cells, makes the lymph flow more freely in the intercellular spaces, thereby diminishing exudates and promoting tissue repair, and it simultaneously dilates the capillaries and causes a more active circulation of blood in the part with all the good effects which that implies. Certain workers who once relieved neuritis and arthritis with the constant current, then with light or the blue pencil brush discharge, are now waxing enthusiastic over the results in similar cases from the use of diathermy. All of these methods have one important effect in common,—the production of *heat* in the deep tissues of the body. Heat by topical applications is dissipated at the surface, whereas in the case of every one of our electrical modalities, the heat generated is as deeply penetrating as the current itself.

If the action of heat is the chief element in the efficacy of so many modalities, it is easy to understand the many good results obtained from the older and cruder types of apparatus as well as present day successes along seemingly diverse lines, and much of the mystery attached to the workings of electricity is at once dispelled. Bearing in mind the great value of the currents causing contractile mechanical effects, both locally in promoting tissue drainage and generally for effects upon nutrition and metabolism, it remains in the average case of localized pain, inflammation or trauma to select for an important share in treatment that apparatus and that modality of electricity which will most conveniently, efficaciously, and safely supply deep and penetrating heat to the part.

Let us think and talk in terms of simple physical effects and do away with the atmosphere of mystery which clings so closely to the thought of electricity. Thus shall we hasten the day when the general practitioner everywhere will feel that it is safe and proper for him to give his patients some of the benefits of this most powerful agency for good.

Nitrogen and Maleness.—Maurel claims that the extra consumption of protein by males brings about a condition of hereditary arthritism, which is indirectly responsible for the inferior number of male births.—*Le Progrès Médical.*

THE MOLOKAI LEPER SETTLEMENT.

By E. S. GOODHUE, M.D., LL.D.,

HONOLULU, HAWAII.

PERHAPS in all Hawaii there is no place so beautiful as the little stretch of land on windward Molokai dedicated to the happiness of its six hundred or more of lepers. Back are the almost perpendicular cliffs of solid rock, softened by trees, ferns, and waterfalls, a magnificent mass rising in some places as high as 2000 feet, and shutting off ingress or egress except by a narrow trail that zigzags its way to the flat and windy top. This trail though hazardous except for the accustomed feet of horse or man, is traveled by the postman four times a week, and by many others who prefer to land on the leeward side of the island.

The plat of land fronting the cliffs one would think providentially selected for the settlement now established upon it, is about three miles long by three wide. Against it breaks a rather noisy surf, and during most of the year a vigorous trade wind blows, the effects of which are seen in the one-sided trees and the good health of the residents of the peninsula.

FIG. 1.—Kalawao, Molokai. U. S. Leprosy Investigation Station near the beach; the other buildings are the various "homes."

At Kalawao, a northern segment where the original settlement was made, are the buildings of the Federal Station for the study and investigation of leprosy. These buildings are practically deserted. The scientific work is done at Honolulu under the supervision of Dr. Currie of the United States Public Health Service and Dr. H. T. Hollman.

Here at Kalawao, facing a sheer wall of rock, is the little church of which Father Damien was curate; near-by an iron railing surrounds his grave. The story of his life, work and tragic death needs no repeating. "Brother" Dutton, almost equally well known, lives within a stone's throw of the church. Upon a greensward of native grass are the Baldwin Home buildings for Mr. Dutton's boys, and the pupils of four brothers of the Church who devote their lives to the care and betterment of these youths.

Mr. Dutton is so well known that a mere mention of his name is all that is necessary. I will state, however, that an appreciation of him by the late Edwin E. Woodman, entitled "Damien and Dutton," and first published in *America*, is well worth reading. It refers to the latter's work as a captain during the Civil War, and to his subsequent entrance into the Roman Catholic Church as a layman, and his work here on Molokai.

Following the beach, now rugged and lava-strewn, now incurved with sand and fringed by reefs, we pass the lighthouse which nightly sends its gleam upon the wave, southward to Kalaupapa, the settlement proper.

The road, which is a very good one, easily traversed by automobiles, was completed a few years ago through the efforts of the superintendent and medical superintendent of the settlement, and by private contributions. Bisecting streets, lanes, and paths are all indicated by neatly printed signboards: McVeigh, Goodhue, Buddie, and other names of significance to the residents.

Among many private residences surrounded by pretty gardens, in some cases owned by the leper occupants, are the McVeigh Home for white lepers and Portuguese; Bishop's Home for leper girls, supervised by Sisters of Charity; Bay View House for blind and other advanced cases, including five new, well-equipped buildings; the Hospital, where the attending surgeon holds his remarkable clinics, and the nursery where non-leprous infants of lepers are taken immediately after birth. Should leprosy develop, they are given back to their mothers. Yesterday the child of a leper father and mother was born and taken to the nursery. After a time these children are discharged and leave the Settlement.

In the town proper are three churches: Roman Catholic, under two priests, one French and one German; Mormon, and Protestant, ministered to by native pastors.

Besides a settlement store, there are smaller private shops, a bandstand for the local musicians, all lepers, and a new music hall and theater. This splendid building, 110 feet long by 40 wide, is well adapted for its purpose, a recreation hall and stage for private theatricals, billiards and other games,

and "movies," for which films are received each Thursday. There is an electric piano, and in the body of the building enough seats are placed for the entire population of the Settlement. Patriotic banners adorn the walls, with local names and mottoes, Aloha, Molokai, Honolulu, Kamehameha, among them.

There is a gallery for non-leprous spectators, where it was my privilege to watch the movies, and what interested me far more, the enthusiastic people below, whose appreciation of the scenes appeared to be keen indeed. All was joy, smiles, and laughter. A spirit of wholesome mirth pervaded the place, and I came away gladdened to know how fully these people could forget their bodily ills. Old men were there, and women, the middle-aged, youths of both sexes, children, mere tots.

Here I met many of my old friends, some of them lepers I had sent to the Settlement from my own district, and it was my privilege before I came away from the Settlement to have something to do with the discharge of a number of them.

The music hall was erected by the Board of Health, but the equipment was secured by private contributions through the efforts of the earnest and indefatigable Jack McVeigh, business superintendent of the Settlement.

Somewhat removed from the leper houses, surrounded by his own grounds, is the latter's residence, close up against that of the medical superintendent and resident physician. Mrs. Gerrould and others recently have told your American public about this capable man and the things he has achieved.

The quality of Mr. McVeigh's work is intrinsic, and when he goes there will be none to take his place, as perhaps may be said of any adequate man; but his works will follow him. Personally, he is extremely susceptible to human appeal, but he is also businesslike, quick, to the point, possibly in some cases brusque. He sees to the pecuniary and business needs of the Settlement, and generally "gets what he goes for," even from such a variable entity as the Hawaiian Legislature, which usually each year makes a junketing trip to the Settlement.

However splenetic this body may feel on arrival here, a few hours spent in the colony makes converts of them all, and they return to grant generous appropriations. Mr. McVeigh is modest, and I will not make an enemy of him by fulsome flattery. I would say that his predominant characteristic is tact, pervaded by a sense of humor.

As the medical superintendent, Dr. Will Goodhue, is my brother, and at this time, with his charming wife, my host, it were perhaps unbecoming of me to say more about him than is already known by intelligent men throughout the world; but I feel that in an article of this nature I should be doing my subject injustice were I to leave out some reference to his great work here. There is a mistaken idea that his residence on Molokai is enforced; that he is a prisoner, confined like his lepers to the rocky shores of his island. This is not so. He may come or go freely, or leave for good. But as he left a lucrative field in medicine because of his interest in the study of leprosy, so he remains because of his love for the lepers themselves, whom he serves day and night, skillfully, kindly, conscientiously, with a tender interest and sympathy I have never seen excelled. Naturally, he is deeply loved by residents in the Settlement, by Hawaiians, Japanese, Chinese, Portuguese, Filipinos, Porto Ricans, Koreans, Germans, French, Belgians, and others who are there.

Great surgeons have praised his surgical work,

FIG. 2.—Baldwin Home, office front; showing many young lepers and Mr. Dutton.

done bi-weekly at his clinics, where remedial and plastic operations of great importance take place. His tracheotomies in lepral stenosis have saved many lives and cured altered conditions of the nose and throat which no other treatment will help. This will be the subject of a later article.

Fig. 3.—Father Damien de Venster.

In this journal, some years ago, was a contribution upon the surgical removal of local leprous lesions, with subsequent cure, a fact well established by the discharge of former lepers now free from the disease. My work in the last week has been to examine and discharge such cases. And while Dr. Goodhue is unusually conservative, and inclined to minimize the value of curative measures carried on by him in this Settlement for 14 years, he readily grants that many cures have been effected, and that the future holds out great encouragement for the relief of localized incipient forms of leprosy. He believes that the nose and tonsils are the most common points of leprous infection, the inflamed mucous membrane of the nose and the

Fig. 4.—Mr. B. Dutton at the age of 20 years.

tonsils offering a rich soil for the reception, growth, and development of the bacillus Hansen.

A number of cases, especially of the anesthetic form, have become self-limited, remaining quiescent, if not cured, for a period of from 8 to 12 years. These have been paroled, subject to inspection at specified periods.

At the usual biennial examination which occurred this month two were discharged cured, and some 14 or 15 paroled for longer or shorter periods before re-examination. A number of others have refused to come up for examination, fearing discharge and subsequent removal from the Settlement, where they have lived for years, perhaps, and formed intimate relationships. One cannot blame them, either. For climatically it would be hard to find a pleasanter place. Their bodily comforts are supplied, food in abundance, and a fair ration in clothes are given them. They may work and earn money, or not, as they please.

"Where do they get their fine clothes?" I asked the doctor, "for most of the women, at least, seem to have the latest styles." "That is true," was the answer, "and I think there is no other institution where individuals receive so many gifts from outside as our people do here. Visitors do not forget us."

Fig. 5.—Dr. Goodhue, servant, and "Buddie."

While unafraid, the doctor is extremely careful about exposure. His lovely home, fronting the cliff and sea, is surrounded by a garden and hedge. A double gate guards the ground, upon which no leper is allowed to come; but at the outer gate there is a bell, lighted at night, to which lepers have free access at all times. The doctor answers any call, at any hour of the day or night, outside of his regular trips to clinics, hospitals, and the homes. The house, in bungalow style, has every convenience. His wife and three children—one little daughter now attending school in Honolulu, and two younger boys—reside here. The former, Buddie, a beautiful and attractive child of 8 years, has become well known abroad through movies in which she is pictured. In their automobile, of afternoons they ride the six miles the area provides, stay for a while at the Beach House, or spin on to Jungle Grove to watch the wild deer upon the cliffs near Kalawao. Or perhaps they climb the trail, and spend a day or so at their Mountain House, at the top of the

pali or precipice, among the trees, for a change of air and environment.

Recently the doctor has selected a plot of low ground, surrounded it by an impervious wall, and will flood about 8 acres for a fish pond. This will be the only inland body of water on the peninsula, and its establishment is giving work to lepers, who receive from $1 to $1.25 a day for their services.

Of course, there is a pathetic side to the life here, but I do not know that it is any sadder than, or so sad, as hospital life, or the life in sanatoriums for the tuberculous. Comfort and happiness smile everywhere. Hope, well based, indeed, reigns in the hearts of many of the incipient and milder subjects of the disease, and when some who are ready to leave may leave, they go with the love and *leis* of their fellows who remain.

This is no charnel house, no graveyard pasture. Death is no more in evidence than it is away from here. People eat and sleep and smile and laugh and enjoy the delights of locomotion. The old grow older in comfort; the middle-aged, in marital companionship, have no worry about future needs; the young joy in their youthful loves.

There is no hanging sword, no danger of suspicion and arrest. The residents are here because they are lepers. It is the non-lepers who feel out of place among their neighbors. No one thinks or talks of the disease. The thing to worry about is an intercurrent malady, or the poor unfortunate who has tuberculosis.

I presume there is no place in the world, no other leper colony, so advantageously placed by nature, and I know none is so tactfully and scientifically maintained, so carefully and conscientiously provided for, so generously endowed, as the Molokai Leper Settlement.

It is an evolution through a series of experiences and processes, to be sure, and credit is due to many men, boards, and legislatures; but it must be conceded that the best ameliorative measures are of comparatively recent date, and are due to the initiative of two or three men.

As I sit here watching the evanescent tints about the sea and cliffs which James Lane Allen has so well described in his "Flute and Violin," a sense of gladness wells up within me, and I feel that the saddest phase of life here is not half so sad as the strife overseas.

THE ETIOLOGY OF GENERAL PARALYSIS.*

By B. LEMCHEN, M.D.,

DUNNING, ILL.

PHYSICIAN TO THE CHICAGO STATE HOSPITAL.

FOURNIER half a century ago was the first to suggest that general paralysis was due to syphilis. He met with quite an opposition at that time from the medical profession, but on further study, and especially lately after the discovery of the Wassermann reaction and the spirochete in the paretic brains by Moore and Noguchi, it is conceded by most authorities that general paralysis is due to a syphilitic infection. What is necessary for us to do is to explain why only about 2 per cent. of syphilitics become paretics. The time allowed for this paper is too short to give all the theories relating to this subject, and as most of these theories have not been accepted, it is unnecessary to repeat same.

As to the latest theory of a different strain of spirochetes having an affinity for nervous tissue—the evidence given of conjugal paresis or conjugal tabes is so meagre in the number of cases that it can hardly be considered, while the long incubation period by itself would speak against it. Do we find such a long incubation period in any of the other infectious diseases of the nervous system, such as cerebrospinal meningitis or anterior poliomyelitis? The incubation period and the course of the diseases are only days or weeks, while from the initial infection of syphilis to the development of paresis, there is a period of from two to fifty years, and the course of the disease also lasts years. Evidently other reasons must be sought for it and this may be due to nature's desire to keep the original species. Had every person exposed to an infection become infected and had the infection run a virulent course or had the invading bacteria always been destroyed by the antibodies, the human race and probably all the bacteria that can live only in human tissue would have long since been destroyed, but nature's desire to keep the original species has accomplished so much that different people will react differently to the same infection. What we should do is to study nature's ways and see what we can learn from them. First there is an individual difference in the local reaction to an invading organism and more so to its toxins. That is why some people may be very sick and even die from an infectious disease, and post mortem will show very few changes, while others with extensive anatomical lesions will live comfortably. We have all seen very severe cases of typhoid fever, which post mortem would show only a few superficial ulcers, while others will have mild typhoid with extensive ulcerations. In fact, the disease is recognized only through perforations. Again, some people will die from tuberculosis and on post mortem only a few small tubercles will be found, while others will live comparatively comfortably with cavities or where the greater part of their lungs are destroyed. Of course had everyone that contracted an infectious disease been overcome by its toxins, where would the human race be to-day? How does the human body protect itself against infectious bacteria? The simplest way is by destroying the organism that invades the body. Nature has provided in all serums a substance known as lysins that will destroy the common parasites, but the dead bacteria liberate a toxin that is responsible for the systemic toxemia, and when too numerous will destroy the host; and the host from cell memory prohibits the destruction of too many bacteria by lysins, but tries some other way by phagacytosis, agglutinins or other means where cell dissolution is not necessary, and also by producing antitoxins to neutralize the toxins; so it can readily be seen that the number of bacteria received at the time of an infection with the rate of their multiplication and the ability of the host to produce antitoxins will have quite a bearing on the future course of that disease because the other protecting bodies besides the lysins must naturally be of a slow formation, and while the producing of toxins is one

*Read at the sixth annual meeting of Alienists and Neurologists, Chicago, July 11, 1917.

way bacteria protect themselves against the host by inhibiting the lysins to destroy all of the infected bacteria, in time bacteria will produce other substances that will protect them against the other antibodies, and the cells of the host also will in time get more resistive to the local action of that organism, and the organism and the host may be so balanced that while the organism will grow in the host, it will not be able to produce its disease in the host.

We have thus what are known as the carriers, and some day some part of the host will get weakened at another part than that part where the organism is accustomed to its local action, and will produce its destruction right there, and that is probably the cause of general paralysis. It is in an individual who has been infected with the spirochetes where to cell memory it was not advisable to destroy them in too great numbers and where the organism and host were well balanced until the nervous tissue underwent some injury either by trauma, alcohol, toxins of other bacteria, autointoxication, or the like, and gave the spirochetes a chance to produce their destructive effect; or in other words, general paralysis is syphilis with lowering of the vitality of the central nervous system, and for this reason we must advise every syphilitic in whom we are not sure that the disease has been cured to live a life that will preserve the normal vitality of the central nervous system by refraining from excessive use of alcohol, tobacco, worry, excitement, trauma, overeating, and excesses of any kind, and above all we must educate the public to the danger of venereal diseases, and the best way of doing this is to teach boys and girls the functions of the reproductive organs.

I may repeat the interpretation of the Jewish Rabbi of the story of Adam and Eve. The Bible tells us that when Adam ate of the forbidden fruit and was reprimanded by God, he stated: The woman you gave me made me eat. They explain it. When God told Adam that his intention was for him to live forever, and because he ate of the fruit of knowledge he would have to die, he answered: "If your intention were for man to live forever, you would not have given him a wife. It is true that you claimed that you made the wife as a helpmate, but that was not the main reason. The main reason why you gave me a wife was for reproduction, as you expected me to die and you wanted to perpetuate the human race, and I figured as long as I am to live in this world only a short time I may just as well possess knowledge. The woman you gave me made me eat it." Every boy and every girl born will live only a short while in this world, and they are entitled to know all about themselves. Then why deny them the knowledge of the functions of the pelvic organs? While the pelvic organs may have an internal secretion that is of some benefit to the body, still their main function is reproduction, and it was nature's intention that the function should be by legitimate marriage as provided by society; and nature in guarding it has armies of bacteria known as *Spirochetæ pallida* and gonococcus that will attack the individual who is not living up to nature's desires, and they are more destructive than the weapons of modern warfare. The best way to impress this on their minds is to take the young men and young women to hospitals for the insane and show them the different stages of general paralysis, and tell them this happens to men and women who violate the seventh commandment.

BALANCING BODY METABOLISM, AND THE QUARTZ ULTRA-VIOLET LIGHT.

By DONALD McCASKEY, M.D.,

NEW YORK.

It is an elemental principle in mechanics that if the inflow through a pipe is greater than the outflow, there is an overflow. We have this principle illustrated in very concrete form during a thunderstorm when the sewage system of a city is unable to carry off the water that falls upon its streets as rapidly as the downpour occurs. This same principle is illustrated in the experience of every housewife in the kitchen when the sink overflows. It is an obvious conclusion, therefore, that there must be balance or perfect equilibrium between the inflow and the outgo, otherwise blockade disorders develop with all the attending phenomena resultant therefrom. The application of this mechanical principle in the physiological chemistry of the human body is likewise quite obvious.

The blood vessels, the lymphatics, the glandular and other cellular tissues of the human body require certain standard quantities of chemicals to pass through them, to upbuild, and to conduct off a balanced amount of waste as a result of tissue destruction.

Take water, for example. If this chemical enters the body in amounts larger than it is eliminated, dropsy occurs. Dropsy is simply an overflow into the human tissues. This same principle applies in the intake and output of any other chemical, for there is no reason under the sun why the nitrogen, carbon, sulphur, and other chemicals that enter into the complex formula of an albumin, or a fat, or a starch molecule, should not be considered upon the same mechanical basis as the hydrogen and oxygen chemicals that comprise the water molecule. This being the case, it must follow that if any of these food chemicals are taken into the body in amounts greater than they are eliminated from the body, the physiological equilibrium of the human tissues is thrown into disorder. As a result, we have the various phenomena that are presented objectively to us by the patient in ill health. To put it in another way, it is absolutely essential for the perfect health of our patients that there be an equilibrium between their processes of anabolism and catabolism. Conversely, as long as these two chemicophysical forces are thrown out of balance the internal machinery of the patient's makeup will likewise be thrown out of equilibrium. This physiological and chemical balance or tissue equilibrium is purely an elemental principle in the mechanics of the human body. It is as fixed as the law of gravity.

Just as soon as this basic law is recognized and the patient given guidance with the specific object of establishing his or her body in a state of physiological equilibrium, any physician holds in his hands the power of metabolism regulation.

The human body might be considered as a great transcontinental railroad artery of traffic, with a demand for multitudinous surveys by the civil engineer for constructive work, with a demand for the solution of any problem that occurs in mechanical or electrical engineering, and all the other forms of organization, executive and administrative work connected with a great railroad system.

The attempt, therefore, to regulate the metabolism of the human body without going thoroughly into the survey phase of the chemical state of equilibrium, would be as futile as for a transcontinental railway president to attempt to succeed in managing his great transportation organization without knowing specifically the basic facts upon which the passenger and freight traffic are conducted; upon the money intake of his railroad and its expense outgo.

In other words, the intake and outgo of money expense on a great railroad system is virtually a financial anabolism and a financial catabolism process. It must balance if the road is to be maintained in a healthy condition over many years.

There are two angles of approach to this problem of bodily anabolism. One is the chemical nutriment value of the food ingested. The other is the assimilation value of the tissue cells that receive this food. There are likewise two angles of approach to this problem of bodily catabolism. One is from the aspect of diet, digestion, exercise, drugs, hydrotherapy, electrical currents, sleep, recreation. The other is through purely afferent avenues. By this I mean the periphery of the human body through the agency of the great skin area with its intricate nerve, blood, and lymphatic supply. By working from without inward, the science of medicine today has advanced its ability to solve this problem of the regulation of metabolism. It is on this phase of the subject, namely, working from without inward, that I shall speak with specific remarks confined to the physiology of light.

We now know that sunlight is divided into three general divisions. First, the Hertzian light wave that is so long in its wave length vibrations that wireless telegraph messages are constantly being sent upon them. We can not see these waves. Consequently, we do not know what color the various Hertzian light waves resemble. The human optical nerve cells in the retina are not attuned by nature to record this molecular vibration. These are the infra-red rays and incapable of producing sunburn.

The second group of light rays from the sun are the luminous group, which the human eye can perceive in the colors of the rainbow, namely, violet, indigo, blue, green, yellow, orange, and red, the wave lengths being the longest in the red and shortest in the violet vibrations. These are the heat rays of the ordinary incandescent electric lamp but are utterly incapable of producing sunburn.

The third group are the actinic light waves. These might be divided into those that produce only a sunburn because of their low penetration power and those which produce a deep penetration, namely, the Roentgen or x-rays.

I shall confine my remarks to that portion of the field of these three groups of light that have to do purely with sunburn. I shall speak of the sunburn actinic rays as produced specifically by the quartz glass light.

It is a fixed principle in the physiology of sunburn that the tissue cells of the epidermis are markedly stimulated and that the peripheral blood vessels are dilated. The lymph channels become engorged and a physical state of localized edema is created with all the other gross phenomena embraced in the four symptoms of inflammation, namely, pain, swelling, redness, heat.

As a result of chemically stimulating the epidermal tissues of the body by sunburn, we have nature coming to the rescue to oppose the invading vibration of these light sunburning rays. Herein is created a marked anabolic and catabolic activity and the metabolism basis of regulation from without inward.

We soon find that the intracellular enzyme ferments have become intensely active with the result that millions upon millions of dark granules are synthetically formed and deposited in the stratum granulosum of the epidermis. There is a resultant marked activity of all the five layers of skin with the exfoliation of the outer or horny layer. These newly synthetized granules of the granular layer contain nature's first line of defense or barrier against the quartz light intruder.

As a result of this increased activity in the metabolism of skin tissues there is formed a more stable and enduring skin structure with all the attending sequelæ of increased blood supply, lymph supply, and likewise peripheral vasomotor and other afferent nerve invigoration.

It is herein that we have made another advance over the purely mechanical-artificial stimulant of massage, of hydrotherapy, or of electricity, for the quartz light sunburn brings about a metabolic reconstructive change of a more or less permanent nature. In the purely mechanical stimulation by hydrotherapy, electrical currents, the luminous or heat rays, and massage, the tissue processes of anabolism and catabolism are but temporary. They lessen as soon as these mechanical stimulant methods stop, and they finally fall back to their original plane of activity.

In the sunburn, however, there is a reconstructive chemical change developed. It continues and increases so long as the light dosage is able to penetrate the skin tissues. This compels nature to form synthetically the black granules in the stratum granulosum of the epidermis and to force continually a new and persistent epidermal growth with exfoliation. Whether there is any reflex stimulation of the internal glandular secretions, especially that of the suprarenals, I have not as yet done any experimental research work to prove or disprove. Clinically, and from purely empirical observation, I begin to suspect that the suprarenals are actually stimulated, but I make this statement with every reservation. Thus far it is entirely a hypothesis and remains to be proven or disproven by future laboratory research work.

So much for the basis of metabolism that can be reached by the sunburn agency.

The proof of the pudding is in the eating. My case records of patients treated for metabolism disorders, in which I have employed the quartz light sunburn therapy as an adjunct to internal chemical regulation, now total 2,000. In no single instance has there been a lack or failure of beneficial results in metabolism regulation. The patient

promptly exhibits marked subjective relief symptoms and phenomena of objective invigoration.

We are yet in the primary grade as to our technical skill in the therapeutic doses of the quartz light upon our patients. By our present methods of application, the dosage of the light must be regulated according to three factors. One is the resistance of the individual patient's skin. The second is the intensity of the light's strength. The third is the period and distance of exposure. Each patient is an individual unit and must be treated as such. To give, for instance, a generalized quartz light sun bath of 3,000 candlepower for twenty minutes at even twenty inches over the entire naked body of an individual as a first treatment would likely put that patient in bed with chills, fever, and a subjective frame of mind extremely irritable and unfavorable to the further employment of quartz light therapy.

Shock results from the quartz light in its initial application just the same as from a surgical operation.

The technique in the use of this vitalizing therapeutic agent must be brought to a more accurate and scientific basis before its most widespread benefits can be available, and I hope in the near future in my clinical and research work with this light to be able to evolve a method of technique whereby we can measure the electrical voltage or resistance of each patient's body so as to be able to know exactly what dose of light per weight is the proper amount to administer to each individual. As it is now, we are dependent purely upon empirical dosage methods of distance and time periods of exposure.

The subject is vast. These observations are merely introductory. In future communications I shall describe the modus operandi of dealing with specific types of disordered nutrition. Certainly, in sunburn therapy from the quartz light we have a powerful and prompt adjunct to metabolism regulation from without inward.

24 West Fifty-ninth Street.

THE PERSISTENCE OF ULCERATION.

J. Van Becelaere, M.D., LL.B.,

Detroit, Mich.

"Any lesion of the living organism tends toward natural repair." At times the process implies a complete regeneration of primary tissues, even reproduction of entire organs, as occurs, for instance, in some of the lower animals (claws of lobster, tail of newt); most often, however, the defect is obliterated by cicatricial structures.

Without attempting a detailed study of the various histological processes involved, it will suffice to mention the proliferation of connective-tissue elements, whose embryonic cells in time undergo fibrous transformation, ultimately resulting in the production of scar tissue.

Any cause interfering with connective-tissue proliferation entails a retardation, perhaps even suspension, of the normal reparative process, in consequence of which the lesion—simple wound that it was in the beginning—assumes ulcerous characteristics. An ulcer may therefore be defined as "any tegumentary lesion that fails of spontaneous repair," and while, in practice, the differentiation is easy as between a simple wound and an established ulcer no one as yet has precisely determined the point at which ulceration begins, nor indicated a pathognomonic feature of the latter. Perhaps exact biopsic findings or determinate histochemical reagents may yet serve to establish this mooted point. Whatever the nature of the changes, the efficient factors in persistent ulceration belong to one or more of several causes, which may be classified either as mechanical, biological, chemical, or microbiological, many of these, however, straddling the classification, and simultaneously coming under two or several heads.

Pressure, for instance—one of the mechanical agencies—acts not only *per se*, but in conjunction with anoxemia, and this is mainly what makes the difference between a corn and a bed-sore.

Again, cataptosis after preparing the ground for ulcerous transformation of a most insignificant tegumentary lesion will maintain such a lesion by continuous tension at the marginal sulcus. Another mechanical factor of no mean import is found in desultory tension at the line of repair, and one can readily visualize a "ragging" of the growing tissues by untoward adhesive bands, or even underlying mobile bony surfaces. This is, I believe, an element, as yet unrecorded, in the persistence of ulcus perforans, and fistula in ano.

By far the most common and efficient factor in the maintenance of ulceration is the presence of parastasis, acting not alone in a mechanical manner by causing and maintaining abnormal intravascular tension, but also through concomitant anoxemia from circulatory stagnation, so that the congested, perhaps even edematous granulation tissue is in the worst possible condition for undergoing reparative changes.

Another no less potent and efficient cause of persistent ulceration hinges upon improper management or faulty technique, inordinate flushing and washing, frequent change of dressings with disturbance of granulation tissue, improper dressing material (protective or gutta percha covering, which retains irritating discharges), but most of all the local use of unsuitable applications, veritable histolytics in character. Irritation incident upon such topical treatment is further increased by possible systemic incompatibility, and one is often in position to bring about a speedy, uneventful healing of protracted ulceration merely by suspending the use of some irritant salve or powder, and substituting therefor almost any bland anodyne application. This is especially the case in syphilitics who often come with a lesion surrounded by a zone of congestion, even of infiltration, and presenting at the margin veritable areolas of medicamentous eczema. And where such marked irritation obtains on the unbroken skin, what must we not fear of such applications acting on the sensitive, delicate elements of budding granulation tissue?

The trend of practice in the management of ulceration is toward the empirical—almost haphazard—exhibition of heterogenous remedies advertised in the press, and I make bold to say that there is perhaps not a single medicamentous agency (from abelmoschus down the list to zedoary) which has not at some time or other been vaunted as a positive cure for long standing ulceration. It is true that some cases do heal under—perhaps even despite—

any form of local treatment; this, however, is but an added proof that nature is of kindly disposition, and merciful unto the suffering.

At the last analysis, however, we must seek in microbiological agencies the key to persistent failure of ulcerative repair. Bacterial organisms inhibit growth of healthy granulation tissue more directly by purloining for their necessary pabulum vital or chemical constituents, the presence of which is essential to the cellular plasma and indispensable to the process of repair, and also by direct poisoning of embryonic elements with excrementitious catabolic products (toxins). Untoward action of bacterial agencies manifests itself indirectly through their nocive influence upon the nerve supply: the vasomotor and trophic innervation. This in part explains the production of interstitial edema, of infiltrative changes, of exudates, and untoward excretions at the wound surface.

Fischer[1] ascribes the lethal termination of nephritis and its complications to cerebral edema, and while he does not express himself in so many words, no doubt the hydration of the vital organs is mainly of chemical origin, and referable to the bacterial toxins circulating in the blood.

The frequent occurrence of stubborn ulceration in cases of lues, tuberculosis, diabetes, etc., is another proof that constitutional dyscrasia, hemic incompetency, the "cacochymia" of the Ancients, is mainly traceable to "impurities" slushing about in the circulatory current; in other words, to the presence of bacterial toxins, generated in amount and at a rate sufficient to compromise natural reparative tendencies.

Adequate curative procedure therefore implies neutralization of hemotoxins, in conjunction with competent local treatment. Nor should we lose track of the fact that not all so-called antiseptics are acceptable. A most instructive tale among la Fontaine's Fables is that of "The Man, the Rock, and the Bear," in which he proceeds to tell us of a certain farmer who captured a bear-cub, and raised him for a pet. The faithful brute, one day, was idly watching his master, asleep in the shade, while a pesky fly made repeated attempts at unwelcome familiarity, persistently landing on the sleeper's face, whereupon the bear, seizing a rock, proposed to swat the fly when he should land again. One fell swoop, and the fly was no more. Neither was the farmer. . . .

Something similar occurs when we attempt by the use of antiseptics to encompass destruction of bacterial agencies at work in a persistent ulceration; granted we kill the germs, what is to become of the delicate granulation tissue, fighting its precarious battle with numerous other factors imperiling its vitality?

To be at all acceptable, any local antiseptic should be of the mildest possible character consistent with the purpose at hand, and it will redound to the lasting credit of Carrel, not that he reintroduced into the surgical armamentarium a preparation advocated almost a hundred years ago,[2] but that he developed a technique enabling him to use the chlorinated lime solution[3] in such manner as to procure aseptization without jeopardizing the patient's welfare.

Medicolegal Notes.

Attending Physician's Right to Fee as Expert Witness.—In an action by a physician for a fee as an expert witness it appeared that the plaintiff, an attending physician and a lifelong acquaintance of deceased, having testified on a prior trial as an expert witness for the proponent, at an agreed compensation of $50 per day, was thereafter employed by a succeeding attorney for the proponent at the same terms, to go over the witness' records to prepare himself so as to give expert testimony on the issue of the deceased's mental soundness, which he did on two trials. It was, however, objected that as plaintiff had been the attending physician, his testimony was not that of an expert, and that such agreement for compensation should not be enforced. It was held that if a medical witness, or other witness with technical qualifications, goes beyond mere testimony to facts observed by the senses, and is asked to draw a technical inference or conclusion, he may properly stipulate for compensation. People vs. Montgomery, 13 Abb. Prac. (N. S.) 207, 240; Barrus vs. Phaneuf, 166 Mass. 123, 44 N. E. 141, 32 L. R. A. 619. Birch vs. Lees, New York Appellate Division, 165 N. Y. Supp. 846.

Refusal of Plaintiff to Submit to Medical Examination.—An unmarried woman 20 years old, residing with her parents but engaged in daily work, recovered a verdict of $25,000 for personal injuries diagnosed by her attending physician as general downward displacement of certain internal organs and traumatic neurosis. On appeal, this was reversed by the New York Appellate Division for the following reason: The court said: "We think that, upon testimony as to the injuries, the defendant is entitled to a new trial unless the plaintiff consent to a reduction of the verdict to $10,000. The plaintiff was not disabled at first by the injury. For a considerable period thereafter she went about her business. She testifies that finally she had to take to her bed. That the medical testimony is unsatisfactory is attributable to the plaintiff alone. With appreciation of her maidenly modesty, we should not lose sight of the fact that she is a claimant for the defendant's money as matter of right. The said physician had qualified himself by an examination of his patient without her knowledge and when she was under an anesthetic. He testified that such an examination was the only method to ascertain the pelvic symptoms. The expert physician called by the plaintiff testified that he could present a diagnosis only as to her nervous condition, for when he attempted to examine the abdominal parts externally, the rigidity of the muscles and the resistance of the patient made it impossible for him to reach any conclusion. The plaintiff admitted that, before trial, she had refused such an examination as was made by her own physician to the physician chosen by the defendant, and she stated at trial that she would not permit such an examination to be made by a woman physician to be appointed by the court. The said physician chosen by the defendant testified that he was permitted to make but a partial examination of the plaintiff, and was refused the right of further examination when he asked for it. He testified that from the examination afforded to him he could not discover any injury. If the plaintiff feels confident that the verdict as reduced is not compensation, and has nothing to fear from a full medical examination, she can take her new trial, and lay aside her present nicety, and submit to an examination without criticism for lack of modesty, certainly if the examiner is a woman. Judgment and order reversed, and new trial granted, costs to abide the event, unless within 20 days plaintiff stipulate to reduce the recovery of damages to the sum of $10,000, in which event the judgment, as so modified, and the order, are affirmed, without costs."—Ringelmann vs. Oscar Daniels Co., 165 N. Y. Supp. 1109.

Military Medicine.

MENTAL DISEASES AND THE WAR.

HOVEN (*Archives Médicales Belges*, May, 1917) states that he does not intend to go deeply into this subject, and contents himself with a brief analysis of the material which has come under his observation as military alienist during the past 14 months. Out of 300 cases, 28 were examples of post-traumatic psychoses such as follow trauma, cerebral commotion, or moral shock. In 11 of the 28 there had been an actual injury to the cranium, while in 12 others shells had exploded close to the victims. Of the 28 patients, 16 presented evidences of mental confusion, and 8 of melancholia. There were 2 cases of dementia precox, one of which the author describes, adding that in post-traumatic psychoses the possibility of dementia precox should always be borne in mind.

With the exception of 24 patients whose insanity dated before the war, the remainder of the material (256 cases) includes the ordinary psychoses of the alienist, viz., dementia precox, 61 cases, and melancholia, 52 cases, followed by acute confusional insanity, with 16 cases, and progressive general paralysis, with 14 cases. Other psychoses occurred only in scattering figures (manic-depressive, mental disequalibration, alcoholic, etc.). However, under ordinary psychoses are comprised idiocy and imbecility, with 62 cases: *i.e.* the mental ailments were found to be associated with subnormal mental development. This contingent was, of course, the result of hasty selection during mobilization. The subjects presented either mental confusion, melancholia, or nervous crises. Latent mental weakness was in part brought out by alcoholic abuse. Those actually insane before the war were mostly volunteers suffering from paranoia, paraphrenia, epilepsy, and alcoholism.

The author states there is no specific war psychosis. The alleged "battle hypnosis" is no more than acute mental confusion with dream hallucination, occurring especially in post-traumatic psychoses. These patients are very wakeful, with an exaltation of psychic automatism and a sensorial erethism. Acute mental confusion is characterized in general by lacunar amnesia, which disappears slowly, and persists after other symptoms have vanished.

Simulation of insanity is rare, but dementia precox often passes at its onset for simulation because the victims indulge in silly, absurd, affected behavior. In true simulation the patient is always abnormal, a psychopath. In contrast with actual simulation, exaggeration is common. Psychopathic deserters are not uncommon, and much care is necessary for the proper fixation of responsibility.

By what mechanism does warfare cause insanity? No one knows now, but after the war is over it may be possible to answer this question. No doubt, insanity is produced by a commingling of psychic and somatic insults. Homesickness, loss of sleep, fatigue, at once suggest themselves, and we may add apprehension of danger, shell concussion, etc. Hereditary taint and history of neuropsychic manifestations are very common; in fact, predisposition in some form is almost universal. In some material, alcoholism, whether as effect or cause of predisposition, is present in a third of all cases.

The practical aspect is diagnostic and not therapeutic. But few of these men are fit for duty, for they can seldom react properly to discipline. They must be mustered out, and, if necessary, interned. The best modern treatment is life in farm colonies, which results in more or less improvement. The inoffensives are able to do useful work for the army in various capacities—basket weaving, shoemaking, woodworking, baking, etc., etc.

WAR RADIOGRAPHY.

THIS subject is pretty well covered by at least one monograph in French, which we believe has already been translated into English. In reading this work, which was pronounced of great merit by experts, we remarked that much of its contents was necessarily of *ante bellum* origin, and that some of the very latest advances in radiography—principally gasless tubes—had not been utilized. It is evident that a completely satisfactory work on war radiography cannot be written until after the termination of the conflict, when the results of specialists from all warring countries can be coordinated.

Meanwhile several periodicals are supplying important data on military radiography. One of these, *La Radiologia Medica*, published at Milan, is very largely devoted to military subjects. In the July-August number of this periodical, four out of seven original articles are of this type. Fiorini writes of gas gangrene and numerous plates illustrate both gas phlegmon and the diffuse type made up of discrete macules or small bullæ. These are brought out in the great majority of cases if very soft rays are used. When present in connective tissue the latter presents an alveolar appearance; while in striped muscle the shadows pursue a course parallel with the muscle fibers. Gas phlegmon is seen as a rule near a fracture; the grouped macules may be distinct or aggregated into a single shadow.

Maffi relates a case of shell fragment in the right ventricle of the heart which it had entered through the inferior vena cava. The soldier had been struck in the abdomen and the fragment had broken the right tenth rib at the median axillary line. The abdomen was tympanic, but there was no peritoneal reaction. The patient complained much of pain in the right hypochondrium. The bowels moved with the aid of glycerine enemas and the tympanites subsided. The first *x*-ray examination was negative. The state of the patient one week after the injury was one of shock and adynamia. The pulse was imperceptible, facies pale and slightly cyanotic, and the patient was totally unequal to voluntary motion. He was now rayed by regions—hepatic, thoracic, cardiac, etc.—still with negative results. The heart could be seen to contract rapidly, with the right side partly obscured by the opaque base of the right lung. Finally, however, a movable shadow became visible in the right ventricle, the motion being of the vortex type. The pericardium was apparently intact, so that the projectile doubtless had reached the heart through the inferior cava. The revelations of the screen could not, of course, be corroborated by an ordinary radiogram. Auscultation and percussion tended to up-

hold the diagnosis. Many colleagues examined the patient who was recognized as acutely anemic while the base of the right lung appeared to be consolidated. The operation of cardiotomy indicated in theory was actually contraindicated by the patient's condition. He was now delirious and blood cultures showed the presence of the streptococcus. Death occurred 12 days after injury. A postmortem radiogram showed that the shell fragment was no longer in the right ventricle, it having migrated into the adjacent pulmonary area at the level of the third intercostal space and three fingers breadth from the sternal margin. Autopsy revealed bloody serum in the right pleural cavity and hepatisation of the base of the right lung. The pericardium and heart were intact and the endocardium showed no trace of irritation. The projectile was found to have entered the pulmonary artery and lodged at the point of bifurcation. It was quite bare, but the artery of the right lung was completely occluded with a thrombus. The liver in the area of the trajectory of the projectile was necrotic and putrid, the suprahepatic vein being included in the process.

Rossi cites 41 cases to illustrate the tolerance of the organism to modern war projectiles. This paper is well illustrated. Finally Coppola describes and illustrates a new operating table for fluoroscopic control.

Skin Diseases and Their Treatment Under War Conditions.—Henry MacCormac states that in the present war the losses occasioned by diseases of the skin have been considerable, and that dermatologists are much concerned with two questions: first, whether the art of this specialist can prevent these skin conditions, and second, when they have arisen how best he can cure them.

In France the problems presented are new; unusual types of skin affection have arisen, while the progress of war, the environment of the army in the field, its ebb and flow and the complicated movements of its being, render impracticable those processes familiar in the quiet habit of civil life.

In dealing with diseases of the skin he says that we are content to know that not only are we alleviating illness, but further, since nearly every case will return to duty, we are able to add considerable reinforcements to the army. We are dealing with men whose health is but little impaired, many of whom are highly trained soldiers, and who from a purely military point of view are of the utmost value to the combatant forces. MacCormac particularly emphasizes this fact because it is so necessary to insist that the employment of the highest skill and best methods are well repaid by the results obtained. The work of a dermatologist is important for a further reason. Where so large a proportion are affected with contagious diseases, the cure of one case may mean the prevention of many others. The problem is no new one. During the American Civil War, out of an army of some 600,000 men, 32,000 cases were diagnosed as itch, and another 35,667 were merely recorded as skin disease. So severe was the former complaint that its pathology was disputed at the time. During the Napoleonic campaign cases of itch were counted by the hundred thousand.

The problem is a serious one. Medical science has curbed many army diseases, but the scourge of scabies still survives to the present time. Naturally, difficulties arise in the treatment of skin conditions on account of the moving forward of the troops over contested ground. In Pais the director of St. Louis Hospital assured the writer that the incidence of scabies in the troops has been greatly lessened since the beginning of the war. This has also occurred among the Belgian Army, due to the establishment of an admirable bathing system and the establishment of dermatological centers in various sections where expert opinion and treatment is available. The French Army has also established these centers and cutaneous affections have been less severe among the French soldiers than among the British soldiers.

MacCormac approves of a scabies station for each army corps. The establishment of these stations would release beds and personnel elsewhere employed in the treatment of skin diseases and each medical officer could deal with a large number of cases and an actual saving would be effected.

Since scabies in France differs in some important features from the form seen in civil life, medical officers must know what to look for. The hands are often entirely free from lesions, while interdigital burrows, that pathognomonic sign, are only present in about 13 per cent. The problem is further complicated by the presence of lesions and itching caused by pediculi. The louse-bitten soldier regards pruritus as a normal accompaniment of his life. The pediculosis is acute rather than chronic and presents a close resemblance to scabies, at times most puzzling. Fortunately the louse never attacks the penis, while this organ is frequently affected in scabies, and the presence of papules or crusts there is of the greatest help in forming a diagnosis. Any system of regimental inspection for the detection of scabies must permit of an examination of the whole body and above all of the penis. Interdigital vesicles rather than burrows should be sought for; impetigo of the buttocks is pathognomonic of scabies, and every patient with boils should be regarded as suspicious, as they form 28.4 per cent. of the pyodermic complications, either alone or associated with impetigo.

The treatment of scabies offers a wide field for discussion. In this prevention is of primary importance. How does a soldier acquire this disease? Dermatologists insist that prolonged and intimate contact is necessary. Since opportunities for removal of clothing are comparatively rare and offer themselves only when in rest, infection must occur at this time, and as it is then that blankets are chiefly used, they may be the means of transmitting the disease. No doubt horses and a venereal origin account for some cases—a small and negligible class. Were it possible to disinfect blankets more frequently, using the Clayton sulphur vapor method, scabies might be greatly lessened. Another source of infection—the importance of fresh cases from England or the base—merits some reference. These men may be removed, but the scabies "carrier," the individual who has been partially cured by methods such as

sulphur fumigation, is a power difficult to deal with.

MacCormac states that under conditions of active service, the best treatment is that which is best suited to the majority, most easily carried out and least expensive. Any system to be effective must fulfill three conditions: burrows must be opened to permit access of the parasiticide to the insect and ova; the parasiticide should be of such a nature as to destroy the parasite without producing dermatitis; finally, to prevent reinfection, contact clothing and blankets must be disinfected. The first of these conditions is achieved by a hot bath, soap, and a soft brush; the second by the application of sulphur ointment twice daily for three consecutive days, and the third by means of any steam pressure or sulphur vapor apparatus. Showers and steam baths are unsatisfactory and almost useless. To attain success the ointment must be thoroughly rubbed in over the whole body below the neck. The soaping and the application of the sulphur ointment must be done under the direction of the medical officer or carried out by a skilled orderly, as the men attempt to apply it with puttees and boots on. Each man should have a separate portion of ointment. Many other remedies, such as balsam of Peru, B-naphthol, etc., have been tried but are not effective. Discovery of the acarus is the only absolutely certain proof that a man is still uncured. But this test is useless in France, for the acarus is extraordinarily difficult to find, even in marked untreated cases.

Brief reference should be made to the impetigo associated with scabies. Its distribution on the buttocks and frequently over the elbows and knees is very characteristic. This impetigo is of an ecthymatous type, and is caused by streptococcal infection; it is relatively common. Those unfamiliar with it are apt to overlook the primary scabies which may be of slight degree. Its presence in no way contraindicates sulphur treatment, which often acts most beneficially. After the scabies has been cured the same treatment is followed as for ecthyma elsewhere.—*Proceedings of the Royal Society of Medicine*, July, 1917.

Tropical Phagedenic Ulcer in French-African Troops.—Simple phagedenic ulcer of the tropics is doubtless confounded with several well-known specific affections, and an account of this affection by Spick in *Le Caducée* for August 15 should be of use in clarifying the subject. When Senegalese soldiers were first brought to France, in 1914, many of these individuals, who had been engaged in railway construction in Africa, were found to be suffering from sores on the feet and legs. In every one of the 129 cases studied by Spick the lesions had originated in abrasions from collision with rails or crossties which the men were transporting. Infection occurred because of complete lack of cleanliness and surgical aid. When these subjects were assembled together for treatment the odor was indescribably repulsive and nauseating, indicating the presence of necrosis. It was impossible to interne the men with other patients, and a separate pavilion was improvised. Generally speaking, the ulcers were multiple, circular, with a tendency to form polycyclic contours. The maximum of extent was that of the palm of the hand. The borders were sharply cut and the floor presented a dirty grayish deposit of gangrene, the thin secretion of which conveyed the disgusting odor. Naturally, the toes, their web, and the adjacent sole of the foot suffered most from the sloughing phagedenic process. Bacteriological tests showed the presence of Vincent's bacillus and spirillum. Treatment, the outcome of many tentatives, was eventually as follows: The ulcers were cleansed with pledgets of cotton soaked in hydrogen peroxide in order to be rid of the sloughs, the scissors also being required to secure the proper conditions for treatment. Upon the prepared surface iodoform was thickly applied. The Paquelin cautery, heated cherry red, was then employed, and served incidentally to set free iodine fumes. More iodoform was now added and sterile gauze applied. After four daily dressings this method of disinfection was repeated. Simple dressings were substituted about the twelfth day, or as soon as all signs of gangrene had disappeared. In some cases toes required disarticulation, and in very severe cases the foot either had to be sacrificed or an extensive use was made of drainage tubes beneath the plantar fascia. Salvarsan was also injected intravenously in seven cases, and appeared to arrest the phagedenic process after surgical methods had failed. The interval between the injections was six days, with an initial dose of 15 cgm., which was doubled, trebled, and quadrupled in the three succeeding doses. Save for the few cases in which relatively extensive amputation was necessary, the men were all back in the ranks in a short time.

Training in Psychiatry for the Reserve Corps.—Beginning with the first week in October a number of officers in the Medical Reserve Corps are taking a six weeks' intensive training in psychiatry and neurology at the St. Elizabeth's Hospital, formerly the Government Hospital for the Insane, under the direction of Dr. William A. White, superintendent, and his assistants. The officers taking this course are: Captains Cyrus Brown Brownrigg, H. R. Carson, R. G. Eaton, William Alonzo Searl, and A. B. Colburn, and First Lieutenants Quintard Taylor, James A. Belyea, John Miller, H. A. Durkin, Emery Low Dravo, and Percy Betterman Battey. A number of enlisted men have also been detailed to the St. Elizabeth's Hospital to be trained in taking care of such cases.

Columbia Base Hospital Opened for Army.—The new base hospital erected on Columbia Oval was formally opened on the afternoon of October 3 with exercises, at which Dr. Nicholas Murray Butler presented the hospital to the United States Government. It was accepted on behalf of the Government by Col. E. R. Schreiner, commanding officer at the hospital. In his address of presentation Dr. Butler said that the building of the hospital was authorized by the Trustees of Columbia University on April 2 and four days later a committee was appointed to take charge of the undertaking. The work of building and equipping the hospital had been rapidly executed and represented "American effectiveness in action." The hospital is receiving soldiers sent home through illness or accident and is prepared at the present time to care for 500 pa-

tients. Plans have been submitted, however, for enlarging it so that it will accommodate 1,000. The building and equipment of the hospital were provided for by a special gift of $175,000 from Daniel G. Reid and $100,000 raised by popular subscription.

British Hospitals Bombed.—A cablegram from the British headquarters in France and Belgium reports that German airmen have dropped bombs on two hospitals behind the British lines. Three British nurses and a number of wounded soldiers were killed.

Flower Hospital to Become a Base.—At a recent meeting of the Flower Hospital War Relief societies it was announced that the Flower Hospital, New York, had made application to be accepted as a base hospital and that this was soon to be granted. Plans have been made for increasing the fund for medical supplies from $10,000 to $25,000 and for doubling the personnel of the hospital.

Red Cross Nurses in Service.—The national committee of the American Red Cross announces that over 2,000 Red Cross nurses are in active nursing service and another 2,000 are in teaching and committee work. Nine thousand more stand ready to serve at once. Specially trained nurses are being held in readiness for work in units devoted to pediatrics, orthopedics, mental diseases, and public health. Infant welfare nurses have already been sent to France and Roumania, and plans are under way for sending a special unit of nurses trained in the care of mental diseases to serve in the mental wards established in the hospitals of 32 cantonments. Since the arrival of the American Red Cross Commission in France last spring an organization of 864 persons has been built up to care for the American expeditionary force and the French people. Of the commission's staff, 517 members are serving without pay or living allowances from the Red Cross. Among these are prominent business men, technical experts, and women experienced in the handling of relief supplies. The average salary paid to the remaining 347 persons on the staff is $800 per year.

Big Red Cross Rally.—The largest body of war nurses ever gathered in this country and the first great Red Cross parade were witnessed in New York City, on October 4. More than fifty chapters of the Red Cross were represented and all the hospitals of the city. Among those leading the parade were Henry P. Davison, chairman of the Red Cross War Council; Major General William C. Gorgas, and Rear Admiral Braisted, surgeon general of the navy. An open air pageant and benefit on the following day netted the Red Cross $50,000.

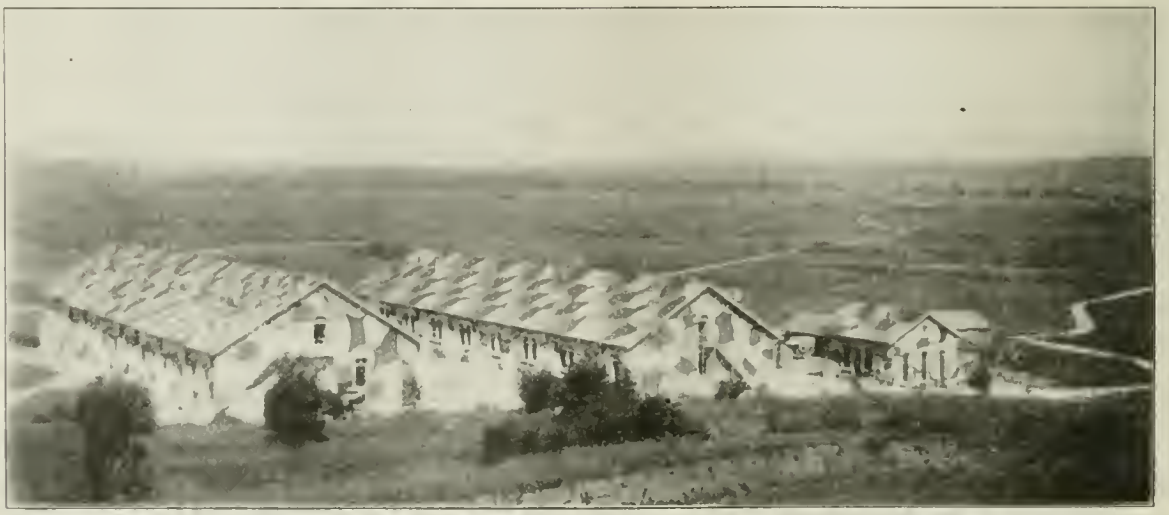
Permament Base Hospitals for France.—The Red Cross has taken steps to replace the temporary structures now used as base hospitals in France with permament buildings which will provide better protection against the rigors of a French winter. Major Murphy has cabled for 2,000,000 feet of fir which is being hurried from Oregon. Other supplies needed in construction are being collected for shipment as rapidly as possible. The American Red Cross has now more than a dozen base hospitals in France, each equipped with at least 500 beds.

Additional Red Cross Activities.—The Red Cross War Council announces that a Bureau of Medical Service of Foreign Commissions to give prompt and expert attention to the requests for medical and surgical supplies received from American Red Cross commissions now at work in Europe has been established. The bureau will also answer requests from doctors and nurses wanting to serve with these commissions, particularly in France and Roumania. Dr. R. M. Pearce of Philadelphia has been made director of the bureau.

Sixteen large warehouses have been completed for the new war relief distribution system in France. Six of these buildings are in Paris and the others in departments outside the capital, and all are said to be filled with supplies.

Another announcement is the appointment of directors of the civilian relief work in each of the thirteen national divisions of the Red Cross. The director of the Atlantic Division is Alexander M. Wilson. Instruction of home service field workers will be provided in twenty-five institutes. These will be opened soon in various parts of the United States.

The object of the home service is to help the families of soldiers and sailors to solve the problems confronting them through the absence of husband or father, and to help them to adapt themselves to the exigencies of war times.



An ambulance station in France; showing the camouflage replacing the Red Cross insignia on the roofs—a change necessitated by the inhuman practice of German airmen of bombing all hospitals and ambulance stations wherever discovered.

Some War Books.

PHYSICAL REMEDIES FOR DISABLED SOLDIERS. By R. FORTESCUE FOX, M.D., Honorary Medical Director of the Red Cross Clinic for the Physical Treatment of Disabled Officers. With Chapters by Major R. TAIT MCKENZIE, R.A.M.C., Professor of Physical Education and Physical Therapy at the University of Pennsylvania; FRANCIS HERNAMAN-JOHNSON, M.D., Senior Medical Officer to the *x*-Ray, Electrical, and Massage Department, Cambridge Hospital, Aldershot, and JAMES B. MENNELL, M.A., M.D., Civilian Medical Officer in Charge of the Massage Department, Military Orthopedic Hospital, Shepherd's Bush; Medical Officer to the Physico-Therapeutic Department, St. Thomas' Hospital. Cloth. Pp. 277, with 88 illustrations. Price, $2.75. New York: William Wood & Company, 1917.

THIS is a valuable summary of physical treatment afforded the sick and wounded in the English military hospitals. It is an early product of rich experience by trained men in the fields of hydrology, electrotherapeutics, radiology, remedial exercises, and training, including massage, passive movement, mechanical treatment, and exercise. Plans of the Heaton Park Command Depot and the department for physical treatment, Military Orthopedic Hospital, Bangour, Midlothian, are included and there is a valuable chapter on the various marine resorts and climates in Great Britain.

So much has been done in England and France to afford physical treatment in suitable cases that in America it is obvious we shall be compelled before long to use the same measures for our returning soldiers. Indeed, we are already making preparation for this reconstructive work. We shall, therefore, do well if we heed the lessons of European experience. No better on the various marine resorts and climates in Great Britain.

Among the newer forms of baths employed are the whirlpool baths. They are local baths of flowing or agitated water, usually at a moderate temperature of 100 to 105° F., or hyperthermal, 105° to 120° F. At the lower temperatures they may be continued for fifteen to forty, or even ninety minutes. They stimulate the arterial circulation in the most powerful manner and both Dr. Fox and Major McKenzie lay great stress on their value. In the French form of bath the movement is supplied by the incoming water under a fifty-foot head; in the British form there is an electrically driven turbine protected by a grating which revolves rapidly at the bottom of the bath. These baths are applicable not only to limbs, but to the entire body and are used in dealing with the stiff and swollen extremities of wounded soldiers. The French are prone to the use of this method which they term "balnéation à l'eau courante."

Another valuable feature of the work is the set of instruments for recording measurements of the mobility of joints and their progress under treatment, and a chart is given for recording these movements as used at the Centre for Physical Treatment at Versailles. It is encouraging to learn that at the Anglo-Belgian Hospital at Rouen of 2020 convalescents discharged after a course of physical treatment, 1170 were completely cured and rejoined their depots; in another hospital out of 3348 soldiers received from disability of all kinds 2676, or 80 per cent., were cured and returned to service. Great stress is laid on reeducation and work and the chapters on massage, passive movement, and exercise by McKenzie and Mennell are illuminating.

LE PALUDISME MACÉDONIEN. Caractères cliniques et hématologiques. Principes de thérapeutique. Par P. ARMAND-DELILLE, G. PAISSEAU, P. ABRAMI, HENRI LEMAIRE. Collection Horizon. Prix 4 francs. Paris: Masson et Cie., 1917.

THIS little work begins with a preface by Professor Laveran, discoverer of the plasmodium malariæ. There is an introduction on the parasitology of Macedonian malaria, chapters on the primary synchromes and relapses and recurrences of the same. The synchromes of secondary paludism are next considered, and followed by the chapters on diagnosis and treatment. Despite the seriousness of the geographical type of malaria, it seems to have been largely overcome by various intensive plans of treatment. It is, however impossible to prevent outbreaks of the disease when summer reappears.

OTITES ET SURDITÉS DE GUERRE. Diagnostic-Traitement-Expertises. Par H. BOURGEOIS, Oto-rhino-laryngologiste des Hôpitaux de Paris, Arbitre-Expert près le Trib. d. Commerce et M. SOURDILLE, Ancien Interne des Hôpitaux de Paris. Collection Horizon. Prix 4 francs. Paris: Masson et Cie., 1917.

AFTER a brief account of non-traumatic otitis as found in soldiers, the authors give due consideration to wounds of the ear and mastoid process and then pass to the vital subject of war deafness from cranial shock and shell deflagration. Special types are described of deafness due to lesion of the auditory nerve paths and hysterotraumatism. The entire subject is summed up in the section on expertisation, which includes a full account of the examinations for audition and equilibration. Not the least in importance are the pages on the relations of impaired hearing to military duty and aviation.

L'APPAREILLAGE DANS LES FRACTURES DE GUERRE. Par PAUL ALQUIER, Ancien Interne des Hôpitaux de Paris, et J. TANTON, Médecin Principal, Professeur Agrégé du Val-de-Grâce. Prix 7 francs 50. Paris: Masson et Cie., 1917.

WHILE the word orthopedic does not occur on the title page, this is an eminently orthopedic treatise; for, aside from the orthopedic management of fractures of the long bones *per se*, the entire subject of the apparatus treatment of resections of bones and joints following projectile wounds is considered along with prosthesis after amputations in the thigh and leg. We note that in the treatment of recent fractures metallic plates are used to some extent, as is also the Hodgen-Smith suspension apparatus. The temporary retentive apparatus for fractures naturally belongs under surgery proper, but the secondary or so-called permanent apparatus is orthopedic throughout, securing unimobilization plus mobility; so that the functions of the limb can be maintained while the bones are not permanently united. Complicated devices such as Delbet's apparatus for fractured thigh are extensively used and the latter has undergone modifications during the present war. The number and variety of single parts which may enter into the composition of these apparatus is surprising. The reviewer obtains the impression that it will become more and more difficult in the future to draw a sharp line between ordinary bone and joint surgery and orthopedics.

FIRST AID TO THE INJURED AND SICK. An Advanced Ambulance Handbook. By P. J. WARWICK, B.A., M. B. Cantab., M.R.C.S., L.S.A., A. K. C., London Major R.A.M.C. (I.) I.D., Commanding 306th (South Midland) Field Ambulance, Lecturer and Examiner on Ambulance, Home Nursing and Hygiene to the Educational Department, London County Council, etc., etc., and A. C. TUNSTALL, M.D., C.M., F.R.C.S., L.R.C.P., Ed. Major, R.A.M.C. (I.), Rtd. Commanding R.A.M.C.'s First Brigade, London Division National Reserve, etc., etc. Tent edition, revised. Price, 80 cents net. New York: William Wood and Company, 1917.

THERE are many extremely good text books on "First Aid," but a lack of concise and well illustrated text books. It was no further back than the year 1901 that Drs. Warwick and Tunstall wrote and published a work with the view of supplying this want. In the sixteen years that have elapsed, the book has gone through ten editions, so that it may be taken for granted that the authors have been successful in this direction. The present edition has been thoroughly revised and brought up to date. In its present form it is admirably adapted to its purpose, which is to give information as to how to render temporary assistance in the most effectual manner to a person suffering from an accident or sudden illness until the arrival of a doctor. The little book will be found quite useful by nonmedical workers in France and on other fronts, and can also be studied with profit by the elders in every household.

MEDICAL RECORD.

A Weekly Journal of Medicine and Surgery.

THOMAS L. STEDMAN, A.M., M.D., EDITOR.

New York, October 13, 1917.

DEGENERATIVE CHANGES OCCURRING IN BICHLORIDE POISONING.

IT is a commonplace that from time to time a wave of suicide sweeps over the land; this is well known by every newspaper reader and especially familiar to the police. When a case of bichloride poisoning occurs, for example, the police department of a great city become immediately on the *qui vive* for a recurrence. Pharmacists are cautioned to be careful about dispensing bichloride, and various other precautions are taken, in spite of which there frequently occur four or five other suicides by bichloride within a short time.

Everyone will recall that several years ago an epidemic of this form of *auto da fe* suddenly materialized, out of nowhere, so to speak. A distressing feature of the situation was the large incidence of fatalities among these cases. In spite of all the remedies known to science, many of these patients seem doomed from the beginning. The spectacular feature of it to the public mind was the fact that some of them went about their daily avocation for a time, apparently well, and then, often a week or so later, succumbed to the poison. Naturally the fact that, even with such a chance for therapeutic effort to be made, these cases went on to collapse and death, was seized upon by opponents of the medical profession as a peg whereon to hang criticism, while the profession itself was not at all satisfied with the state of affairs, and strove to discover some remedy for such a situation.

The natural assumption was of course that profound organic changes of some sort must take place in the patient shortly after the ingestion of mercuric chloride, otherwise the intensive elimination usually carried on would soon rid the patient of the poison. This view is borne out by an article by Drs. W. H. Burmeister and W. D. McNally (*Journal of Medical Research*, March, 1917), who have made extensive studies of the changes taking place in the viscera in bichloride poisoning, especially in the liver and kidneys. As they point out, too often the intensive inflammation of the digestive tract, while a distressing symptom, is given much attention to the comparative neglect of the more important renal and hepatic changes.

Why these organs should be so profoundly affected has not been clearly understood hitherto, although several theories have been advanced. The most popular ones have been those which held that the injury was directly caused by the irritant action of this poison as it was eliminated. The latest opinion seems to be that there are local vasomotor disturbances plus direct injury of the parenchyma cells by the mercurial compound.

Drs. Burmeister and McNally studied the kidneys, liver, and colon of 14 dogs poisoned by corrosive sublimate. Not to describe their experiments in detail, it can be said that they were very thoroughly and accurately performed. The chief conclusions drawn from them were: (1) That mercuric chloride can be detected in the blood a few minutes after it is taken. (2) Similarly quickly, degenerative changes appear in the kidney, going rapidly on to cell-death. (3) When large amounts have been taken there is a corresponding effect on the kidneys; when smaller doses have been taken kidney changes depend on the length of time; in large doses liver changes do likewise. (4) The degree of kidney and liver changes is not necessarily proportionate to the amount of mercury in the blood.

These experiments show clearly why so little effect has been seen with energetic therapy in bichloride poisoning. The poison seems almost at once to seek out the kidneys and liver and institute degenerative changes which go rapidly forward. Our problem then must be to prevent this rather than to concentrate our entire energies on hastening elimination.

SUCCESSFUL TYPHOID PROPHYLAXIS.

IN spite of the great success achieved in the reduction in the morbidity from typhoid fever through better water supply, supervision over the sources of food supply, and other sanitary and prophylactic measures, every so often there is an outbreak of the disease in a community paying the maximum attention to these matters. That this is a source of worry and discouragement to many goes without saying—as is the case with the present typhoid epidemic in one of the boroughs of New York. But before accusing a community of negligence in the care of pertinent matters it must be remembered that there is a "normal" increase of typhoid fever in the autumn—hence the name, "autumnal fever." Much of this increase must be attributed to direct importation from distant rural communities where city people are wont to spend the summer in large number and where the sanitary provisions are usually inadequate. On the other hand, infection of even one person, no matter where the source, who handles food can set up a considerable epidemic. The infected individual need not be at the source of supply, and an intermediary handler of food may be difficult to trace because his contact with the food is so very transient. The typhoid contracted directly from consuming infected food, such as oysters, will follow no definite geographical

lines, because the consumption of such food follows no definite lines but is rather scattered. But in the case of water, and particularly of milk or milk products, the line of infection is usually well marked and confined to the lines of distribution. Many of the water and milk epidemics have for this reason been run down easily. Infections that are originated by active typhoid cases are comparatively easy to trace to their source, but the trouble in the detection of the human cause of the epidemic lies in the fact that it is the apparently healthy carrier who is the chief source of infection. Against carrier infection general sanitary prophylaxis seems impotent, because the carrier is hard to detect and because he is himself innocent of the danger he harbors.

Formerly, in searching for the source of an epidemic water was given first place. Yet in communities like New York that have a highly developed and protected water supply the danger from this source is negligible. Even in less protected communities the water supply is the slightest offender. Unless the pollution of the water supply is at once sudden and overwhelming water can dispose of a good deal of infectious material. Flowing water, especially aided by sunlight and sedimentation, soon frees itself of even a great deal of pollution. Moreover, the dilution of the infected material in a stream is usually great and any individual can imbibe only a small dose at the worst. This is not meant to minimize the danger from polluted water nor to discourage the expensive methods for the purification of the water supply, but rather to put the likelihood of infection from water in its proper place. On the other hand infection from food, especially milk, plays a large factor in the spread of this disease. In this case neither the flux, sedimentation, dilution, nor sunlight can play any part, and infection therein has an opportunity to exert a direct and maximum force. The direct contamination of food by flies and other insects must, of course, be borne in mind. In the case of milk or other food the infection directly by carriers or by those attending upon actual or undiagnosed cases is perhaps the largest factor in the causation of typhoid fever. And yet while all the elements of prophylaxis against this disease, such as adequate water purification, supervision over food production, general sanitation, education, etc., have helped to reduce the incidence of typhoid fever they have not succeeded in eradicating the disease. Indeed, these measures can be a delusion and even a snare. No army would now think of depending wholly upon such extrinsic elements in protecting itself against typhoidal infection. The only real and successful safeguard against the disease is antityphoid vaccination. This was amply demonstrated among the troops on the Mexican border and is being imposed upon the present overseas army. Should antityphoid vaccination be carried out as universally as vaccination against smallpox the former disease would soon be just as great a rarity in civilized communities as the latter.

OSSEOUS ANOMALIES.

For some occult reason the idea of a person or part of one becoming petrified has for ages been hailed as exquisitely mirthful. Any slang term which can embody this concept in a succinct manner is sure to become popular. Thus we have the application of such terms as "solid ivory" and "concrete dome" to those whose intellect, it is alleged, functionates slowly, or who are guilty of acts whose wisdom can be questioned. There is also a very general lay notion that a human being can "turn to stone"; casting back into our own youthful memories for a criterion, the conception of this process would seem to be a gradual stiffening and hardening of the flesh—general, not local—finally culminating in a sort of statue, whose only human attribute is that it exercises reason. More picturesque still is the popular idea of an ossifying process beginning, say, at the toes, and simultaneously, or soon thereafter, in the finger joints, and creeping upward, slowly, steadily, implacably, until it reaches the heart, when the individual of course succumbs.

Such famous practical psychologists as the lamented P. T. Barnum, of glorious memory, the idol of a generation or two of youthful worshippers, were not slow to see the possibilities in this outré conception, and one of the chief stand-bys of the sideshow and the dime museum has been the "petrified man," the "man of stone," and so on. Of course many of these cases are frauds, or have some other affection than real progressive ossifying myositis, which is a great rarity. The real disease seems to have been first described by John Freke in 1741, but the first accurate description was by Münchmeyer, who, in 1869, collected from his own experience and the literature twelve cases. The disease is sufficiently well known now, although of course, in most cases, only from hearsay, by the great majority of the profession.

In a recent article, E. L. Opie* has reawakened interest in this subject by a classical description of it. After discussing the literature, Opie describes the skeleton of a seventy-year-old man who had had this disease. In the same periodical, Opie, collaborating with Nathaniel Allison, describes a kindred disorder, hypertrophic chondrodystrophy, where the abnormal production of osseous matter occurs within cartilage. A number of illustrative cases are described. There is nothing to indicate that these two disorders result from any inflammatory process, rather must we regard them as perversions of the normal osteogenetic process. The cause is obscure, and probably will remain so until that time—should there ever come such a time—when we obtain some real insight into the creative power which gives to the protoplasm sentience.

*Progressive Muscular Ossification (Progressive Ossifying Myositis)—A Progressive Anomaly of Osteogenesis, by Eugene L. Opie; and Hypertrophic Chondrodystrophy in Infancy and Adolescence—A Progressive Anomaly of Osteogenesis, by Eugene L. Opie and Nathaniel Allison, *Journal of Medical Research*, May, 1917.

Treatment of Wounds by Soap.

Lucas Championnière was one of the first to draw attention to the value of soap as an antiseptic, and since then more or less use has been made of it for this purpose. In the *Medical Press* of August 15, 1917, Dr. M. Palynski gives his experience with soap in this relation. It must, of course, be of good quality, that is as devoid of impurities as possible. The manner in which Palynski has employed soap is by lavage, irrigation, and local application in saturated compresses. For lavage and irrigation a solution of 25 grams to the liter of boiled or distilled water was used. According to the author, the modes of action and advantages of such a preparation are as follows: On contact with the sanious or fungating surfaces of infected wounds, soapy solutions produce a viscid, stringy fluid of an opaline tint. The cleaner a wounded surface is, the less is the exudate of viscous fluid. Thus, on the other hand, all anfractuous wounds, and especially those of compound fractures, yield an abundant discharge of that kind of fluid. This characteristic secures, to some extent, the effect of making the soapy solution a reagent by the aid of which we can discover the presence of pus in those remote cul-de-sacs and inaccessible interstices, the draining of which is rendered physically impossible by their position. A compress, impregnated with a 20 per cent. soap solution, never causes any pain or smarting in the surface it touches. Simultaneously with the appearance of the viscous exudation, the congestion of the tissues of the wound begins to subside under the influence of the soaping and where there has been a bleeding point, the capillary hemorrhage ceases. It would seem, indeed, that with its mild, non irritating, alkaline, and antiseptic properties, the dressing possesses no injurious influence, whatever, on living tissues. It acts as a porous dressing which sucks away the pus as fast as it is formed. The stratum of minute air bubbles imprisoned between the tissues of the gauze realizes to a marvelous degree the condition essential for capillary drainage. At the same time, the alkali, in virtue of its avidity for liquids, contributes very effectively to the desiccation of the surrounding tissues. The dressing should never be covered up with any form of impermeable material.

"Medical" Treatment of Abscesses.

The possibility of preventing the formation of abscesses even after considerable pus has begun to accumulate has been freely discussed in past ages. To cite two examples, we may mention scrofulous abscesses in the neck region, and carbuncles. In each of these processes there appears to be a critical point at which suppuration may be arrested before the collection of a large amount of pus. Surgeons and pathologists are naturally sceptical as to any abortive action on suppuration, and look on such suppression as apparent rather than real, but intensive local and general antiscrofulous treatment sometimes seems to check the beginning suppuration in a cold abscess, just as the act of pushing calcium sulphide inwardly often appears to check acute suppurative processes. To-day, perhaps hardly any one believes in the policy of arresting such pus formation, even were such a result obtainable. The dangers of absorption and metastasis are so numerous and varied that prompt elimination of the focus is regarded as most urgently indicated. The entire subject seems to be revived in connection with the possibility of suppressing abscesses of the liver of presumably dysenteric origin with injections of emetine. The use of ipecac in this condition has been discussed for nearly two centuries, but tropical abscess of the liver is not a momentous subject with dwellers in temperate zones, except those in countries having colonial possessions. There is an article by Brocq and Auge in the *Revue de chirurgie* for August, 1917, on the successful treatment of acute hepatitis with expected abscess formation without resort to the knife, in which three cases are narrated, the probable nature of which was amebic. It is admitted that the knife alone cannot cure hepatic abscesses, but a combination of emetine with simple puncture is often successful in these cases, for the alkaloid changes living pus to dead pus through its amebicide properties, and the dead pus can be readily evacuated with a trocher. In the authors' cases, since no puncture was used, we can infer that pus had not yet formed, or that after sterilization it simply underwent retrograde changes. No doubt this possibility will eventually be cleared up by autopsy finds.

The Fasting Cure of Diabetes.

Recent works on this subject by Kellogg of Battle Creek and Stern of New York award the chief credit for this innovation to Guelpa of Paris, which may be just, so far as the calendar goes. But the work of Allen of the Rockefeller Institute, though published a year or so after Guelpa's clinical reports, has a sure scientific foundation, including results of animal experiment; hence it evens matters up when Professor Sabrazès, the distinguished clinician of Bordeaux (*Gazette hebdomadaire des sciences médicales de Bordeaux*, August 12), appears to give the American full credit for the scientific—as contrasted with the empirical—*raison d'être* of the fasting management of diabetes. We have never understood why any one should begrudge to Allen the credit to which he is abundantly entitled in this connection, nor can we understand how Stern, in his recent work, can ignore Allen so completely that—if we do not err—the latter is not even granted the courtesy of a passing reference. Kellogg gives some space to Allen's work, yet since he began the fasting treatment as soon as he had learned of Guelpa's experience, he may perhaps be excused for not expatiating on the former. On the other hand, the work of Joslin of Harvard is more or less confused with that of Allen. The former appears to have evolved a near-fasting treatment before 1908, and he was the first, or one of the first, to give Allen's work a fair test in practice, so that to-day the Joslin and Allen methods agree very closely. The name of Naunyn is often seen in connection with the evolution of the fasting treatment of diabetes, and it is to be hoped that the question of priority in this regard will eventually be permanently settled to the credit of all just claimants. The same problem seems inevitable whenever a really epoch-making discovery is made in any branch of applied science.

Paraffin in Burns.

Researches into the antiquity of paraffin in the treatment of burns do not appear to have been made as yet, perhaps because the rock-oil industry is comparatively modern. However, vegetable paraffins have been known for a much longer period, and according to Dr. Luis Espin (*Revista Medica Cubana*, July 1) some form of paraffin was recommended for burns as far back at 1797 by a Scotch practitioner. The remedy soon passed into oblivion, but was revived in England in 1834, only to meet with a like fate. Next in historical order comes the work of Barthe de Sandfort, with his "ambrine," and, following this, numerous preparations with open or secret formulæ. Espin states that he obtained the old Scotch and English formulæ (the last named is from the London Hospital) and devised a new preparation on a paraffin base which has given him surprisingly good results in the first case tested. The formula is as follows: Subnitrate of bismuth, 0.8 gm.; oxide of zinc, 10 gm.; beechwood creosote, pure, 3.5 c.c.; vaseline, 70 gm.; paraffin, 160 gm. Following the practice in Scotland, he began by using a brush on the burn and then applying the remedy warm and allowing it to cool. As this dressing is not claimed to be highly antiseptic, the burn should first be treated with a solution of hydrogen peroxide. A layer of cotton is then superposed on the paraffin coating. The author omits to state either the old formulæ or the references to the original reports, but doubtless a research into the older literature of the treatment of burns would unearth similar procedures.

Tartar Emetic and Malaria.

Quinine, although regarded as a true specific in the treatment of malaria, is by no means curative in all cases. It is pointed out in the *Interstate Medical Journal* for September, 1917, by Dr. M. D. Levy and Dick P. Wall that in estivoautumnal infection quinine fails almost entirely. Rogers stated some time ago (*British Medical Journal*, January 6, 1917) that tartar emetic injected intravenously had an inhibiting action on the plasmodia in malaria, and Levy and Wall, on the strength of this statement, gave the method a trial, the results of which they summarize as follows: In the few cases reported by them, tartar emetic used intravenously in comparatively large doses had no ill effect upon the circulatory apparatus. In cases of tertian malaria it reduced the temperature and apparently relieved the patient, though it did not cure him, as plasmodia were present in the blood stream after rather large doses of the drug. While no conclusions could be drawn, it seemed that in tertian malaria, at least, tartar emetic was not as efficient as quinine. However, the authors promise further experiments with the drug in the treatment of estivoautumnal fever and will report upon their results in a later paper.

The Administration of Emetine.

Emetine is now largely employed in therapeutics and especially in the treatment of amebic dysentery, and it almost always is given hypodermically. This mode of administration, however, causes intense pain, with redness, swelling, and induration. Writing in the *Lancet* of August 18, 1917, Dr. P. Figdor recommends intramuscular injections of emetine. He thinks that the best sites are on the upper arm over the deltoid and in the gluteal region. According to his experience a prolonged course of treatment can be given in this way without causing any inconvenience to the patient. There is no pain, though sometimes there is a little tenderness at the site of injection for twenty-four hours or so. Injections can be given on alternate arms day by day. Briefly summarized, Figdor believes that the advantages of the intramuscular method are as follows: (1) Pain during the operation is limited to the prick of the needle; (2) After-pain is generally absent, and when present disappears within 24 to 48 hours; (3) There is no tenderness, swelling, induration, or discoloration of the skin, and scarring is minimal or absent; (4) The efficacy of the drug may be increased, as there is probably less precipitation through more rapid absorption; (5) The same site may be used for injection indefinitely at intervals of 48 hours.

News of the Week.

Government Control of Manufacture and Sale of Narcotics.—As a result of recent disclosures in reference to the criminal drug traffic in this city, the Federal Grand Jury has recommended in a set of resolutions, unanimously adopted, that the entire manufacture and sale of opium, heroin, morphine, and other narcotics, be placed under the direct control of the Federal Government. The Grand Jury urges inspection of every plant where drugs are manufactured; that the product be shipped to Government warehouses, in zones to be established; that the Government should control the prices, the quantities shipped to wholesale druggists, jobbers, dealers, retailers, and pharmacists, all of whom should be bonded and licensed; and that the Government should control exports and imports. The Grand Jury has asked that the matter be taken up with the Department of Justice, so that an adequate bill may be presented to Congress.

The Feeble-minded in New York State.—As one of the first steps necessary to the better control of the problem of the feeble-minded, a joint committee of the State Charities Aid Association and the New York Committee on Feeble-mindedness has prepared an estimate of the number of feeble-minded persons in New York State. The estimate places the number at 35,000, of whom 6,000 are in institutions established for the feeble-minded, 4,500 are in other institutions, and 24,000 are at large in the community. Those making this investigation believe that these figures are in themselves sufficient evidence of the inadequacy of the present institutional accommodations in New York for this large class of individuals.

Street Deaths.—The report of the National Highways Protective Society for the nine months ended September 30 shows that in New York State 636 persons were killed, as compared with 543 and 476 for the same periods of 1916 and 1915. In New York City, automobiles killed 46 persons, trolleys 5, and wagons 4, during the month of September. In New Jersey, 29 persons were killed by auto-

mobiles during the month. During the first nine months of the year 190 deaths were caused by automobiles, as compared with 171 for the same period of 1916. In Detroit, said to be the most dangerous city in the United States in which to live, an average of one person a day has been killed for the past two months. The figures show that car accidents in that city have increased 100 per cent., and automobile accidents 185 per cent.

Lay Cornerstone on Randall's Island.—The cornerstone of the first of a group of eleven buildings now in the process of construction on Randall's Island was recently laid by Mayor Mitchell. These buildings are being erected by the Department of Charities, and will be known as the Institution for Feebleminded Children. Bids will soon be asked for three more buildings.

Hospital Needs Funds.—The New York Ophthalmic Hospital has made an appeal for $10,000 with which to keep its work up to the standard. The appeal states that the war is adding to the number of blind and deaf, and the institution wishes to be prepared to do its part, especially since the directors have placed it at the disposal of the Government.

High Cost of Milk a Health Problem.—The Health Department of New York City believes, in view of the relation of the cost of milk to child welfare, that it should concern itself with the present high price of milk. It has already made inquiries, which are still under way, among families of the poor, which indicate that the use of milk has been greatly restricted because of the increased price. It has been found that the sales of milk for family use have been decreased 20 per cent. in some districts. It has also been found that for purposes of economy some mothers have bought milk for their children of a lower grade than is considered safe for infant feeding, and that this has undoubtedly been a factor in the increased infant mortality of the past summer. Health Commissioner Emerson has called the attention of Mayor Mitchell to these facts, and has suggested that the city schools, baby health stations, settlement houses, hospitals, dispensaries, and police stations, might with propriety be used for the distribution and sale of milk, bread, and perhaps other staple foods whose cost to the community is now excessive. At the request of the commissioner, the mayor has appointed a committee to elicit all the facts in relation to this matter and to make constructive suggestions.

Work of Rockefeller Foundation in China.—The annual report of the China Medical Board of the Rockefeller Foundation, which has just been presented, states that two medical schools were founded in 1916 at Pekin and Shanghai, planned on American and European lines. Appropriations totaling $158,502 were made to missionary hospitals at Nankin, Huchow, and Canton. An appropriation of $50,000 was made to the Tsinanfu Medical College and $30,000 to the Hunan Yale Medical College. The report states that the work of establishing these medical schools has been somewhat delayed by the lack of facilities for giving students the proper premedical training, and quite a number of the appropriations made were to institutions promising to further general and premedical education.

Dr. Egbert H. Grandin announces the removal of his office to 200 West Fifty-eighth Street, New York City.

The George F. Geissinger Memorial Hospital of Danville, Pa., has received an endowment fund of $1,000,000 from Mrs. Abigail Geissinger.

Dr. Jonathan Leigh of Hiawatha, Kan., celebrated his one hundredth birthday anniversary on September 24. Dr. Leigh continued in active practice until ten years ago.

Dr. W. W. Crawford has been appointed health officer of the city of San Diego, Cal.

Prof. James McKean Cattell of the Department of Psychology in Columbia University, has been dropped upon the charge that he had disseminated doctrines tending to encourage a spirit of disloyalty to the Government of the United States.

"Euthanasia" Again.—In accordance with the inexorable cyclic law, a revival of the discussion on the killing of the old, the infirm, and the hopelessly ill is now due, and promptly on time comes a Des Moines physician with the familiar proposition. The legalization of the practice was urged by the doctor at the annual meeting of the American Association of Progressive Medicine, in Chicago, on September 24. It gained for him a fifty-line notice in the *New York Times* the following day.

The Missouri Valley Medical Society, at its meeting in Lincoln, Neb., on September 21, elected the following officers: *President*, Dr. A. I. McKinnon of Lincoln; *First Vice-President*, Dr. T. M. Paul of St. Joseph; *Second Vice-President*, Dr. Paul Gardner of New Hampton, Iowa; *Secretary*, Dr. Charles Wood Fassett of Kansas City, Mo.; *Treasurer*, Dr. O. C. Gebhart of St. Joseph, Mo. The next meeting of the society will be held in Omaha, in September, 1918.

The Increase of Insanity.—An article in the *Modern Hospital* points out that whereas the population of the United States has increased 11 per cent. between 1904 and 1910, the number of persons in insane asylums has increased 25 per cent. during this same period.

Typhus in Serbia.—A cablegram from Jassy, in Roumania, announces that the American Red Cross Commission has arrived there at a most opportune moment, as typhus fever has broken out again and is making headway in various villages.

Obituary Notes.—Dr. DAVID GORDON ALLEN, Assistant Surgeon, United States Navy, died on board the *Panther* on October 3, aged 38 years. He was a graduate of the College of Physicians and Surgeons, New York, in 1903, and was appointed Assistant Surgeon in the Navy in 1908.

Dr. BENJAMIN M. PAGE, a practitioner of medicine in Pasadena, Cal., since 1887, died at his home in that city, on September 18, aged 74 years.

Dr. HARRY VERNON WEAVER, a graduate of the Boston University School of Medicine, in 1893, died at his home in New Bedford, Mass., on September 22, aged 47 years.

Dr. J. N. RILEY died at his home near Stamping Ground, Ky., on September 20, his ninetieth birthday. He was a surgeon in the Confederate Army and practised medicine in Central Kentucky until he was 80 years of age.

Dr. BRADBURY M. RICHARDSON, a graduate of the New York Homeopathic Medical College, in 1865, a

member of the American Institute of Homeopathy and the State Homeopathic Medical Association, died at his home in Brooklyn, September 23, aged 75 years.

Dr. EDWIN SHARP, a graduate of Vanderbilt University, Nashville, in 1881, for many years a practitioner of Argenta, Ark., died in a sanitarium in Hot Springs, after a long illness, on September 25, at the age of 65 years.

Dr. JOHN HENRY ELLISON, a graduate of Vanderbilt University, Nashville, in 1888, died at his home in Altoona, Ala., on September 27, aged 55 years.

Dr. MOORE MOORE, SR., died at his home in Grenada, Miss., of cerebral hemorrhage, on September 24, aged 70 years.

Dr. JESSE R. JOHNSON, a graduate of the Memphis Hospital Medical College, in 1894, died at his home in Amite, La., on September 24, aged 52 years.

Dr. BENJAMIN F. FORTNER, a graduate of Vanderbilt University, in 1872, formerly of Springfield, Mo., died at Vinita, Okla., September 24, aged 70 years.

Dr. EMMA MEHLMANN, a graduate of the University of California, in 1908, died of acute leucemia, in Oakland, Cal., on September 20.

Dr. CHARLES W. NUTTING, a graduate of the Atlanta Medical College, in 1876, died at his home in Etna Mills, Cal., on September 22, aged 65 years.

Dr. HENRY L. WILSON, a Confederate veteran, and one of the oldest citizens of Atlanta, Ga., died after an illness of several months, aged 78 years. He was a graduate of the Atlanta Medical College, in 1876, and the first city physician of Atlanta.

Dr. LACY KINDRED BOBO, a graduate of the Louisville Medical College, in 1889, died of cerebral hemorrhage, in Dallas, Tex., September 20, aged 66 years. He formerly practised medicine at Oxford Junction, Iowa, and later removed to Maquoketa, Iowa.

Dr. R. M. HARGETT, a retired physician of Versailles, Mo., died on September 24, aged 87 years.

Dr. HENRY GILBERT LEE of Petersburg, Va., died suddenly at Blue Ridge Summit, Pa., on September 22, aged 50 years. He was a graduate of Bellevue Hospital Medical College, New York, in 1891, and was for many years city coroner of Petersburgh.

Dr. ROBERT MCALLISTER RICHARDSON, a graduate of the Chattanooga, Tenn., Medical College, in 1908, died at his home in Chattanooga, after a lingering illness, on September 19, aged 37 years.

Dr. BRADBURY M. RICHARDSON, a graduate of the New York Homeopathic Medical College, in 1865, a member of the American Institute of Homeopathy, died at his home in Brooklyn, N. Y., on September 23, aged 76 years.

Dr. PETER HUGHES of Brooklyn, N. Y., died at his summer home at Milford, Pa., on September 30, aged 60 years. He was a graduate of New York University, in 1879, formerly demonstrator of anatomy in New York University, visiting surgeon to St. Catherine's Hospital, Brooklyn, St. John's Hospital, Long Island City, and St. Mary's Hospital, Jamaica, L. I.

Dr. MARCUS LAFAYETTE NANCE, a graduate of the Medical Department of Tulane University, in 1905, of Utica, Miss., and later of Osola, Miss., died September 20, aged 43 years.

Progress of Medical Science.

Boston Medical and Surgical Journal.

1. Foreign Bodies in the Eyes. John F. Curran.
2. The Chinese Barber and His Use of Aural Instruments. A. M. Dunlap.
3. Results in Further Study in Leg Rotation. C. L. Lowman.
4. Carcinoma of the Umbilicus. M. G. Wohl.

1. Foreign Bodies in the Eye.—John F. Curran states that since the establishment of factory hospitals it is the industrial surgeon who treats the majority of cases of foreign bodies in the eye, and it is from his point of view that Curran presents this subject. At the Norton Company during the past year 1300 cases of injury to the eye were treated; of these 90 per cent. were directly attributable to foreign bodies. In fact, they constituted one-third of the entire number of cases treated at their hospital, and were second only, in frequency of occurrence, to lacerations of the upper extremities. The method of examining the eye for foreign body is as follows: First, the lower conjunctival sac is inspected. This is done in the ordinary manner, by pulling down the lower lid, and telling the patient to look up, thus exposing the whole conjunctival surface. The upper lid is next inspected. The lid must be everted. To do this easily, have the patient look down, grasp the lashes of the upper lid, place an applicator at the base of the tarsal cartilage and evert the lid, thus exposing the entire fornix. The cornea is next examined. If necessary a watchmaker's glass may be used, or the eye illuminated obliquely through a condenser. Large foreign bodies can usually be seen with the naked eye, but small ones require a prolonged search with artificial aid. If the eye is first put at rest by the instillation of two drops of a 4 per cent. solution of cocaine, the examination can be conducted with greater ease and expediency. Two conditions may arise to cause confusion: First, pigment spots in the iris, and, second, pigment stains, or rust spots. Rust spots are the result of the imbedding of foreign bodies in the cornea. Curran leaves the rust spot for the time being, after having removed the particle, and in the course of forty-eight hours the spot in its entirety can be removed. In the treatment prophylaxis is of the utmost importance. Goggles should be worn by the workers wherever there is danger of flying particles. Their hospital records show that in 50 per cent. of the imbedded cases the foreign body is in the cornea, 5 per cent. in the sclera, and in the remaining 45 per cent. it is found loose in the conjunctival sac. Removal of foreign bodies lying loose in the conjunctival sac can usually be accomplished by means of a cotton-wool applicator. Two drops of argyrol, 20 per cent., are instilled and the patient discharged. Imbedded foreign bodies, whether situated in the cornea or sclera, always necessitate the use of an anesthetic. Two drops of a 4 per cent. solution of cocaine in a boric acid solution are used. A corneal spud usually removes the offender without difficulty. Technique for removal of large foreign body imbedded in cornea is thus: Eye cocained, lids held apart; foreign body located. Point of cornea spud introduced as nearly as possible between the foreign body and the corneal tissue. The foreign body is then elevated and removed with a swab, in case it slips from tip of spud, as it frequently does. A Graeffe cataract knife is used to remove small foreign bodies. After the removal of a foreign body is accomplished routinely there is instilled two drops of a 20 per cent. solution of argyrol because of its antiseptic and astringent properties. If much conjunctivitis is present or pain the following is frequently used: Cocainæ hydrochloridi gr. 1, glyceriti borici 51, aquæ camphoræ 31. One or two drops are instilled every hour or two, and the patient is advised to use hot compresses at home. When a foreign body which was imbedded is removed two drops of a 1 per cent. solution of atropine is always instilled to put the eye at rest. The injured men are supplied with colored goggles, and Curran states that the men seldom lose time even when the injury is extensive. He considers that the number of such accidents has been reduced to a minimum by the use of goggles which are now being worn throughout the factory. The goggles not only directly protect the eye

but deflect many blows which otherwise might permanently injure the eyesight.

7. Treatment of Sclerotic Middle Ear Diseases with Radium.—Zdenko Von Dworzak states that the middle ear diseases which he holds suitable for radium treatment are the catarrhal adhesive process and otosclerosis proper. In both of these diseases there have to be dealt with obstacles in the sound conduction in the tympanic cavity. The etiological factors are about the same in both diseases. The clinical diagnosis is at times difficult, and the prognosis in all cases is doubtful. As organized disease processes in the middle ear have to be dealt with, a return to the normal is almost impossible. Up to the present the prognosis in cases of typical otosclerosis has always been very unfavorable in view of the anatomical changes in the labyrinth cavity. The therapeutic object has been to stop the rapid progress of the disease, to lessen if possible the head noises, to eliminate the disagreeable head symptoms, and if possible to improve the hearing. Up to the present no method of treatment has accomplished any great result, and Dworzak states that it would be a real blessing if the activity of radium with its destructive and stimulating qualities would give a new remedy to combat this distressing condition. For the treatment he uses the radium rays as well as the radium emanation. The use of the latter he considers is original with him. He applies it directly in the tympanic cavity, as the tympanum offers much resistance to the rays, like all other fibrous membranes. The amount of radium varies from one to ten mgm. radium element. The radium tubes are applied by means of the radium applicator and are centered in the ear by means of the head band, to which is attached a small ear speculum by which it is possible to introduce and remove the applicator and to watch the reaction. A brass filter eliminates the alpha and beta rays and the therapeutically active gamma rays penetrate the tympanum and middle ear. Besides this, he employs a larger amount of radium to ray the entire ear region. He considers the effect of the radium to be purely destructive here in eliminating the proliferating pathological tissue and partly in a selective action on the terminal nervous ramifications. The radium emanation he manufactures in an emanator of special construction. Out of the tank oxygen bubbles through the liquid in the bottle which contains the radium in solution. The quantity of this oxygen is nicely regulated. The oxygen takes up the radium emanation and can be used for inhalation, by means of a mask or in room, for the activation of water for drinking purposes or for the treatment of the ear directly in blowing it through the Eustachian tube in the middle ear. In the latter case Dworzak employs the pressure of the oxygen alone or combines the emanator with the Meyer-Rowan instrument, so that sound waves or air under pressure will force the emanation into the tympanic cavity. At times the patient inhales the radium emanation and he also inflates the Eustachian tube by Valsalva's test. In all cases it is necessary to remove the excess radium emanations after treatment by means of suction from the external auditory meatus or by pressure through the Eustachian tube or both combined, for radium emanation remaining in the middle ear could ultimately cause damaging after effects. Radium D, one of its products of decomposition, lasts sixteen years, and might remain active too long in the middle ear. The radium emanation acts like a strong and active ferment and therefore it deserves a prominent place in the treatment of internal diseases, especially as we have no other means which brings about such an intense oxidation effect. In the course of the treatment three phases can always be recognized: 1. The pathological symptoms become more severe and general unrest is exhibited by the patient. 2. Later a constant euphoria sets in and all the symptoms of the disease disappear. 3. Finally a supersaturation seems to arise with insomnia and unrest, occasionally accompanied by the old pathological symptoms. An intermission in the treatment causes a disappearance of these symptoms in a few days. Dworzak cites four cases out of fifty-three similarly treated by the above method. In almost all the cases he found either an improvement or a complete cure—in twenty-two cases—of tinnitus. In twenty-four cases there was striking improvement in the hearing; in eighteen cases, a slight improvement; in seven cases there was no reaction whatever. The rest of the patients—four—left town before treatment was completed. Dworzak calls attention to the fact that radium is not a panacea, but a valuable remedy in combination with other known methods of treatment.

5. The Importance of the Ligaments of the Ankle in Correction of Congenital Clubfoot.—Isadore Zadek and E. L. Barnett announce that it is generally conceded that the best time to begin treatment in cases of congenital clubfoot is within a few weeks after birth. The usual method of correcture is employed, using plaster of Paris, braces, or adhesive tape, to maintain the proper amount of correction obtained. While this suffices in a large percentage of cases to effect the desired results, it does leave a large percentage still uncorrected. It is with the element of equinus that they have been chiefly concerned. While the clubfoot may be practically overcome, the child stands and walks without being able to put his heel squarely on the ground. To overcome this, they have followed by means of the Roentgen ray the relative effect of section of the Achilles tendon and the posterior ligaments of the ankle joint, as regards the freedom of dorsal flexion of the foot immediately afterward and the positions assumed by the os calcis. They were unaware of the case with which the posterior ligaments of the ankle can be cut subcutaneously, and their first case was done under the fluorscope. The technic employed has been to use a tenotomy knife with a long shank and small blade with a cutting edge only on one side. The knife is inserted on the inner side of the ankle just at the inner edge of the Achilles tendon, and on a level with the tip of the internal malleolus. The back of the blade is turned inward. After penetrating from a quarter to half an inch, depending on the age of the patient, the blade is turned so as to lift the vessels, nerves, and other structures up on its back, and the blade is pushed deeper. Maintaining this position, the blade is swept outward from the internal malleolus while pushing up on the foot. There is an audible and palpable grating while the sawing motion is in progress. After all the resistant structures have been cut, the tenotome is withdrawn and the foot is pushed up. There is a give and sometimes an audible cracking. Now one finds the os calcis tilted un. Thus far they have treated in the manner described twelve club-feet.

They would caution against using this procedure soon after manual correction has been attempted, as the foot broken and weakened at the mediotarsal joint will give at this point, and thus will not allow sufficient leverage to obtain the desired dorsal flexion of the foot as a whole. They draw the following conclusions from the results of their investigations: (1) One of us, from observation of several hundred cases of congenital clubfoot treated by the usual methods, has noted that practically none of the severe cases shows dorsal flexion to a right angle without breaking the mediotarsal joint. In view of this observation of failure to procure sufficient dorsal flexion to insure stable locomotion, this operation has been devised. (2) From a study of these cases by the Roentgen ray we conclude that the only reliable test for the correction of the equinus if there is a rounded sole is a roentenogram. Many cases which have shown apparent overcorrection, when studied by the Roentgen ray show a break at the mediotarsal joint, with the malposition of the os calcis not rectified. These are the cases which later, never having had the equinus over-corrected, gradually become worse and constitute the early "relapsed clubfeet."

12. **The Treatment of Epidemic Poliomyelitis with Immune Horse Serum.**—E. C. Rosenow announces that opportunity to test the effect of this serum in patients presented itself during the present epidemic of anterior poliomyelitis at Davenport, Iowa, and surrounding community. The routine procedure consists of making a spinal puncture for diagnostic tests and for relief of abnormal pressure, and of injecting the serum. From 5 to 30 c.c. of spinal fluid are allowed to escape, depending on the age of the patient and the amount of pressure. The fluid is made to flow slowly. The cell count and Noguchi's globulin test are made at the bedside, and if positive, the injection of serum is given at once. The serum is activated with complement by adding one part of fresh guinea-pig serum to nine parts of the immune serum and incubating at 37 degrees for one hour. It is then diluted with equal parts of 0.85 per cent. salt solution. The diluted serum is injected slowly into a suitable superficial vein not later than thirty-six hours after activation. Approximately 2 c.c. of the mixture are injected per minute of time. The dose is varied according to the age of the patient and the severity of the symptoms. Babies from about 1 to 2 years of age are given from 3 to 7 c.c. of serum at each injection, that is, 6 to 14 c.c. of the mixture; children from 2 to 5 years of age from 7 to 10 c.c., and older individuals from 10 to 20 c.c. The injections are repeated in from eight to twenty-four hours if necessary. Every patient in whom the diagnosis is definite, and the disease still active, is given injections of serum irrespective of the severity of symptoms. Altogether forty-four patients have been treated. Of these nine died, a mortality of 20 per cent. Of the nine fatal cases, six were moribund, or in a dying condition from respiratory failure at the time the serum was given, and hence should not be included as treated cases. Of the thirty-eight patients in whom there was sufficient time for the serum to act, three died, a mortality of 8 per cent. One of these was a baby 11 months old, semicomatose with spasms eight days after onset of the illness when the serum was first given. One, a boy 2 years old with cyanosis, marked tremors, high fever, severe gastroenteritis, and beginning respiratory paralysis on the second day at the time of the first injection; and one, a girl 11 years old, with high fever and paralysis of the face on the third day when the first dose of serum was given. Of these thirty-eight treated cases, twenty-two showed definite paralysis when the treatment was begun, and sixteen were in the preparalytic stage. Excepting the three fatal cases in the former group, paralysis appeared to be arrested in all but one, a boy 5 years of age, in whom a moderate paralysis developed in the left leg, the first injection of serum being given on the second day of the disease. All of the sixteen cases treated before paralysis had begun recovered without paralysis. These results are in sharp contrast to the twenty-three untreated cases which occurred during this epidemic of which nine patients died, a mortality of 35 per cent. The apparent good effects from the injection of serum are often striking. The headache, nervousness, restlessness and tremor often disappear promptly. The temperature and pulse rate are lowered. A beginning paralysis often disappears in an astonishingly short time. A rapidly progressing paralysis is often arrested and improvement is unusually rapid. The post-paralytic pains do not appear or are comparatively mild. It is believed that the unactivated serum would do good, and that intraspinal injections might be given with benefit, but since the activated serum and intravenous injections have given the best results in monkeys, and are yielding such splendid results in patients, Rosenow has not felt justified in changing the method. Intravenous injections in this epidemic appear especially desirable because the gastrointestinal symptoms are so pronounced. It is, of course, realized that many more patients must be treated before conclusions can be drawn as to the exact value of this treatment. Of its harmlessness and apparent good effects, there can scarcely be any question. There is on hand enough serum to treat approximately 800 patients. Suitable quantities will be sent gratis on request to physicians or laboratories for reports of cases in localities where poliomyelitis now exists in epidemic form.

2. Purulent Bronchitis: Its Influenzal and Pneumococcal Bacteriology.—Adolpe Abrahams, Norman F. Hallows, J. W. H. Eyre, and Herbert French describe a type of bronchitis, not following the usual classical symptoms and clinical history, which they state has impressed all who have had the opportunity of engaging in military practice in the Aldershot Command for any length of time. These cases are of a definite type, clinically recognizable almost at sight, yet different from anything they have been familiar with in men of military age in civil life. To this peculiar type of case they have given the designation "purulent bronchitis" on account of the characteristic nature of the expectoration. They call attention to these cases for two reasons. In the first place, the affection has a very high mortality—very much higher than that of lobar pneumonia; secondly, there are features and circumstances which suggest an epidemic nature. A typical case is as follows: The onset is usually acute; the early symptoms correspond to a "cold in the head." Temperature may be 101° or 102° Fahr., but there are no distinguishing features by which to diagnose the condition from the ordinary cold. At this stage two or three days later two features attract attention. First the character of the expectoration: this consists of thick pale yellow dollops of almost pure pus, not the frothy expectoration of ordinary bronchitis; it has no particular odor, and it becomes increasingly abundant until in a day or two it may amount to several ounces in the 24 hours. Secondly, the rapidity of the patient's breathing: this may be so evident that pneumonia suggests itself, yet on examining the chest the only physical signs consist of a few or many rhonchi scattered widely, but most marked at the bases of the lungs behind, associated with wheezy vesicular murmur; resonance is unimpaired and bronchial breathing absent. A little later a peculiar dusky heliotrope type of cyanosis of the face, lips, and ears appears, so characteristic as to hall-mark the nature of the patient's malady even on superficial inspection. Dyspnea becomes pronounced; respiration consists of short, shallow movements, which in bad cases amount almost to gasps, reminiscent of gas poisoning. Recovery at this stage may occur, but by the time the cyanosis has become at all marked the prognosis is extremely bad. Character of the sputum remains the same throughout, occasionally it may be blood-tinged. The condition is not

primarily a lobar or bronchopneumonia, but a bronchitis. Microscopical and bacteriological examinations show that it seems not unlikely that these patients suffer from a primary invasion of their lung tissues by the *B. influenzæ*, and that pneumococci, present at the same time, are at first of low virulence. The earlier symptoms seem to be attributable to a *B. influenzæ* toxemia. Exaltation of the virulence of the pneumococci by a symbiotic growth with *B. influenzæ* would appear to follow, a fatal termination being due to pneumococcal septicemia.

La Presse Médicale.

August 16, 1917.

Causes of Pan-Germanism.—Helme quotes from a recent address on this subject by Dr. Sanarelli, the well-known hygienist. The original impetus was very ancient, and founded on advantages of climatic nature enjoyed by the Celto-Latin peoples, who possessed clear skies and prodigal soil, and no tendency to overcrowding. Deprived of these advantages, the German peoples were compelled to develop industrial life, and the desire for conquest. So-called culture began with Kant's teaching that perfect social order is the final expression of culture, an interpretation which apparently holds good to-day. This sentiment gave rise to a dangerous altruism—dangerous because all people, Germans as well as non-Germans, must be enslaved "for their own good." Socialism and Pan-Germanism both hark back to the same sources, but represent the extremes of democracy and autocracy. Even when the French held Prussia during 1805-1808, Fichte, the philosopher, then at the height of his fame, insisted that Prussia was the educator of the human race and identified the German peoples with humanity. German vanity must, therefore, be well-nigh indestructible and proof today against hunger and privation. Hegel upheld the State against the individual; Schelling thought German destiny was the destiny of the human race; Schlegel that the German peoples sum up all the good qualities of alien folk. "Did they not possess the artistic tastes of the Italians, the logic of the French, the historical genius of the English, the poetry and patriotism of the Spaniards?" Schleiermacher, the theologian, caps the climax when he says, speaking for Germany, "I will take possession of the universe." It was only necessary to transform philosophy to science to make possible the present war.

Arterial Tension in Aortic Insufficiency.—Amblard sums up his article as follows: Even without the aid of the ear one may affirm the existence of aortic insufficiency by evidence which in any case could not be supplied by the stethoscope. If a patient has a minimum tension of 65 mm. of Hg. and a maximum tension of 165 he surely is suffering from this condition. In cases recognizable by the stethoscope it may be possible to determine whether or not the affection is specific simply by the minimum tension whenever the latter at least equals constantly the normal minimum. If this minimum is about 100 in a known case of aortic insufficiency we can almost certainly pronounce the case one of syphilitic aortitis. In the same manner we can appreciate the progress of the disease, and in connection with the rapidity of the pulse can predicate the functional condition of the myocardium. The author has worked on this subject for 10 years (his graduation thesis was devoted to daily fluctuations in blood pressure), but neglects to state what apparatus he uses for determining blood pressures.

Journal de Médecine de Paris.

August, 1917.

Syphilitic Origin of Fissured Tongue.—Gaucher refers to the predilection of syphilis for the tongue; for this affection may give rise to mucous papules, sclerous glossitis, leucoplasia, and so-called scrotal tongue, the last-named being congenital, and a dystrophy rather than a disease. In this affection the tongue is always enlarged, with its mucosa thrown into folds which resemble somewhat the cerebral cortex (whence the term cerebroid tongue). The author is thus particular to describe this condition, because it is diametrically unlike fissured tongue in the strict sense of the term; for in this affection the fissures are superficial and the tongue small rather than large. In scrotal tongue the normal median groove is deepened, and branches are given off which subdivide and intersect. In fissured tongue a similar state of affairs exists in miniature. The grooves have a similar arrangement, but the ramifications are so shallow that the finer ones are readily overlooked. Fissured tongue is not a congenital dystrophy, but a so-called quaternary phenomenon of syphilis, like leucoplasia—a sequel of active syphilis. But while it is usually acquired it may also appear as a form of rather late inherited syphilis. In the latter form it may be associated with leucoplasia, geographical tongue and the denture of hereditary syphilis. In the fissured tongue the normal median furrow is somewhat deepened and branches are given off as in scrotal tongue. The principal difference is seen in the fact that fissured tongue is made up in part of isolated grooves, while the furrows as a class exhibit a tendency to form straight lines and curves instead of the symmetrical arrangement of furrows in the scrotal tongue, which has been likened to that of the veins in a leaf. The author cties eight cases of simple fissured tongue in syphilitics. The first patient was a young girl, daughter of a paretic, aged 11 years. Her tongue was not enlarged, and exhibited shallow, irregular furrows on both dorsum and edges which could be emphasized by passing the finger over them. The second patient was a young woman referred by a dentist. The Wassermann was positive, and the diagnosis was "fissured and geographical tongue." The case was evidently hereditary. The third patient, a middle-aged man, knew himself to be a victim of hereditary syphilis, and gave a positive Wassermann. His teeth showed stigmata, and he also presented leucoplasia and an irregularly fissured tongue. The remaining patients all had acquired syphilis of many years' standing, and presented the characteristics of fissured tongue. To take a case at random, patient No. 8, aged 57, had contracted syphilis at 18. He seemed to be in perfect health, but the normal median furrow of the tongue was deepened and crossed by three transverse grooves, while at either half of the dorsum there were isolated curved longitudinal fissures.

Le Progrès Médical.

August 18, 1917.

The Luetin Biopsy.—Tzanck and Bernard refer to the employment of luetin in the diagnosis of late syphilis—the older the syphilis the greater the percentage of positive reactions. Luetin may be regarded as a vaccine of dead cultures, killed mechanically, but containing all the syphilis toxines. When a subject with old syphilis is vaccinated the local reaction may be expressed by a papula, pustule, or indolent lesion, which is also pustular. False positive reactions may occur from imperfect technique. The only other disease which has given true positive reactions with luetin is leprosy. To exclude the possibility of false positives biopsy is required with histological study. In a true positiv the epidermis presents no change. The derma stains its elastic fibres, and of the cellular infiltration a third, at least, of the cells are plasma cells. The dominant element is the giant cell which may be seen isolated in the infiltration or in a caseated zone beneath the derma. They are usually numerous, and many of them typical. If pus is present they may be found in a drop of pus without biopsy. The latter should be performed about the tenth day.

The Codex of Effort.—Dr. Bellin du Coteau uses this expression as synonymous with the record of an athletic contest. The effort may be merely intense—corresponding to our sprint and short distance races—in which case a great deal depends on the start; or intense and prolonged (as in middle distance running). When the distance is a mile or more the effort is only relative. In a sprint the pulse rate is 160; in a middle distance race it may reach 220. In a relative race it is about 140. A sprint is over before there can be any reaction in the brain. The runner does not feel the effort he is making, but the fatigue is pathological and exceeds that in the mile or relative effort. A distance

of 400 meters is traversed with almost as great a speed as one of 100 meters. The first 150 meters equal a sprint race, but during the last 250 the runner must use his volition to hold his pace. Hence, at this distance a psychologic element is present—the will must offset the fatigue of the heart. Finally, in the relative effort the runner is an ordinary human being, who reasons, and uses certain tactics with mind relatively free. He has to antagonize inevitable choking up with respiratory products and slowing of the muscles.

Revue Médicale de la Suisse romande.

August, 1917.

Indicanemia, Symptom of Renal Insufficiency.—Tchertkoff refers to the recent progress of our knowledge of azotemia. Retention of nonalbuminous nitrogen was known even to some of Bright's contemporaries and there are numerous old studies of the subject which, however, led to conflicting conclusions. Strauss was the first to arrive at harmonious results, and to revive the flagging interest, and Widal and Javal distinguished between chlorine retention and nitrogen retention. It was recognized by Weil that the latter means something more than excess of blood urea. Two other substances, creatinine and indican, began to receive attention. It was shown that uremia of a certain clinical type was not dependent on nitrogen retention—eclamptic, or pseudouremia. It was also learned that "considerable degree of nitrogen retention could occur without the development of uremia; and that in such cases a strong indicanemia could be present. Conversely uremia could occur with but little urea retention, and in such cases indican could be absent from the blood. The technic for measuring blood indican is somewhat complicated, and this fact has led the author to devise a more simple method. He punctures a vein to obtain 8 or 10 c.c. of blood serum, adds an equal quantity of 20 per cent. trichloracetic acid, and filters. To 10 c.c. of filtrate he adds an equal amount of concentrated HCl, containing 5 grams per liter of perchloride of iron. The mixture is then shaken and 3 c.c. of chloroform added. During the next 15 minutes the mixture is shaken several times. If indican is absent no coloration appears. If present a pale to dark blue color is manifest, varying with the amount of indican present. This method is also of value for the recognition of iodine in the blood, the presence of which is shown by a rose or rose violet color. The two reactions tend to cause confusion, and no test for indican should be made on patients who are taking iodides. The amount of indican is estimated by control color solutions. The test is so simple that no practitioner can afford to omit it. If indican is present at all it implies an azotemia of about 1.5 per cent., and always means renal insufficiency. If the patient have chronic nephritis it signifies a fatal ending within a few months—often a few weeks. In certain of these cases the blood urea is barely increased. Azotemia is by no means synonymous with uremia.

A New Cause of Hematuria—Phosphaturia.—Perrier reports four cases of hematuria in which the only demonstrable cause of association was phosphaturia, the former subsided when the latter had been corrected by treatment. The exclusion was as follows: Tuberculosis, through several inoculation tests; calculi by *x*-rays; tumors by the parallel efficiency of the two kidneys; nephritis and pyelitis by the negative evidence; hemophilia on general principles, etc., etc. How does phosphaturia contribute to hematuria? It certainly does not do this necessarily. The author cannot even suggest a mechanism to explain the association.

Correspondenz-Blatt für Schweizer Aerzte.

August 25, 1917.

Blood Transfusion.—Klinger and Stierlin review a number of the methods in use and give the results of personal experiments on animals. They had devised a citrate method which is practically that of Lewisohn of New York, but at the time were ignorant of its existence in literature. In animal experiment they learned that *in vivo* the citrates do not affect the coagulability of the blood. When injected into the circulation some unknown × prevents it from "paralyzing" the blood calcium. We can only explain this phenomenon by the supposition of rapid oxidation. This hypothesis has been partially sustained by experiments *in vitro*. This discovery does not prejudice the value of citrates in transfusion, for the method leaves nothing to be desired unless in hemophilic cases, in one of which the authors successfully used transfusion with normal blood. Transfusion is indicated after all severe blood losses when serum alone is insufficient. A certain degree of loss of hemoglobin makes the need of transfusion imperative. The most urgent indication is in hemophilia. In recent years in European clinics septic conditions attended by severe anemia have benefited by transfusion. There is a great need in such cases of erythrocytes which are able to function. We cannot, of course, be sure that these cells do not produce their good effects after disintegration.

The Neurosis Problem in the Light of War Neuroses.—Imboden discusses Oppenheim's new book on war neuroses. The latter makes four disease forms—pure hysteria, neurasthenia, hysteroneurasthenia, and traumatic neuroses in the narrower sense. Neurasthenia cases show as a whole closeness to type—monotony in symptoms, as excitability, exhaustibility, sleep disorders, general weakness, headache, vertigo, tachycardia, exaggerated reflexes. But it is not easy to draw a sharp line between this affection and hysteria, on the one hand, and hysteroneurasthenia on the other, despite the great variations and lack of type in these two affections. Many independent clinical affections have to be placed under one or another of the four groups, and as nervous tics, akinesia, amnestica, reflex paralysis, myotonoclonia trepidans, etc. Such affections fit most naturally into traumatic neroses which is in part a residual group. Oppenheim recognizes three principal causal elements or mechanisms—mechanical shock, psychic shock (akin to fright), and ideogenic motivation. Here emotions and ideas are sharply differentiated as causes. Oppenheim believes psychic shock a far more common causal factor than ideogenicity, the latter, in fact, being very rare. The two mechanisms are so different that it would be a great error to confound them. Emotional shock acts powerfully on the visceral nervous system, causing somatic symptoms. In traumatic neuroses mechanical shock is by far the leading causal factor, hence a truly organic basis must often underlie these syndromes. Naturally the pronounced views of Oppenheim are meeting with more or less criticism at the hands of his colleagues.

Poisoning by Vaseline Oil.—Salomon reports cases in a woman and two children in which such symptoms as nausea, cardiac oppression, cyanosis, and somnolence ceased upon the discontinuance of applications of liquid vaseline. Analysis of the latter failed to discover the noxious principle.—*Correspondenz-Blatt für Schweizer Aerzte.*

Snapping Neck.—Lanz describes the case of a man of thirty-two who when rotating his head in extension—which was done only with pain and effort—elicited a snapping sound. Operation revealed an anomaly of the spinous process of the fifth cervical vertebra, which on rotation rubbed against the spinous process of the subjacent vertebræ.—*Zentralblatt für Chirurgie.*

Treatment of War Erysipelas. — Mild and medium cases in the experience of Capitan yield to relatively mild, symptomatic remedies, local and general, such as ointments containing salol and antipyrine, quinine, and cardiac and renal stimulants. In severe cases he has used collargol and antistreptococcus serum. Large doses of the latter prove abortive in some cases.—*Revue de Médecine et de Chirurgie Pratiques.*

Aspiration Drainage in Infected Wounds.—Grimberg has applied a method used for treating empyema to infected war wounds. After preliminary irrigation with Dakin's fluid a simple suction apparatus is applied, to wit, a bottle with two tubules of which one is connected with a drain while the other has a stopcock. The bottle having been filled with water the stopcock is opened slightly and water begins to escape, creating a vacuum into which there enters slowly the discharge from the wound.—*La Presse Médicale.*

Book Reviews.

THE FUNDUS OCULI OF BIRDS ESPECIALLY AS VIEWED WITH THE OPHTHALMOSCOPE. A Study in Comparative Anatomy and Physiology. By CASEY ALBERT WOOD. Illustrated by 145 drawings in the text; also by sixty-one colored paintings prepared for this work by ARTHUR W. HEAD, F.Z.S., London. Price $15. Chicago: The Lakeside Press, 1917.

THE colored plates in this work are grouped at the end of the text and include three of reptilian fundi. The work, published as a quarto, is the outcome of ten years of study, and is apparently the first serious effort to depict the fundi of birds in a comprehensive and systematic fashion. The avian eye is the highest expression of vision among the vertebrates. So great is the diversity of the fundus in species that it is often possible to identify the latter by the former. Attempts to photograph the fundi of birds in natural colors have thus far resulted in failure. The eyes of domesticated and captive birds are of no value for study, for they have undergone material alterations as a result of disuse; for the fundi of the wild bird are especially adapted to seek food, to escape from natural enemies, for migration and reproduction. The reptilian fundus, as would naturally be expected, closely resembles the avian fundus. The most conspicuous object in the avian eye is the pecten, which springs from the optic disk and projects to a greater or lesser extent into the vitreous. It may be flattened or cylindrical, and in the latter case sometimes extends completely through the posterior chamber. A study of the avian fundus is very largely a study of the pecten. These often possess a most striking and suggestive appearance. Thus the pecten of the laughing kingfisher as seen by the ophthalmoscope resembles at first sight a centipede. In various species it resembles a pine cone, and also often recalls a tightly coiled snake. We do not find the fundus of the buzzard of the South, so famed for its preternatural sharpness of vision, but even the most enthusiastic scientist might be excusable for declining to study this scavenger at close range. The book is of course beyond all praise.

HEALTH SURVEY OF NEW HAVEN. A Report Presented to the Civic Federation of New Haven. By CHARLES-EDWARD AMORY WINSLOW, JAMES COWAN GREENWAY, and DAVID GREENBERG of Yale University. Price 75 cents. New Haven: Yale University Press, 1917.

THIS survey comprises the sanitary condition of the city, the health organization, and the vital statistics. The mortality runs slightly higher than the average of registration cities. The infant mortality agrees closely with that of New York City. The death rate from typhoid fever seems unnecessarily high in contrast to that of a number of cities. In spite of an analysis of the morbidity nothing has been found to work upon, *i.e.* the drinking water and milk supplies are not at fault. The only factor in evidence appears to be the habit of bathing in the polluted harbor water. Results in lowering the death rate of tuberculosis are gratifying. Pneumonia seems unusually deadly in New Haven, while for cancer the mortality is not only unusually high but increasing. A third extensive cause of deaths is the degenerative disease of advanced years. These three causal factors cannot be reached by sanitary activities.

ROENTGEN TECHNIC (Diagnostic). By NORMAN C. PRINCE, M.D., Attending Roentgenologist to the Omaha Free Dental Dispensary for Children, Associate Roentgenologist to the Douglas County Hospital, etc. With seventy-one original illustrations. Price $2. St. Louis: C. V. Mosby Company, 1917.

THE author, who is roentgenologist to a number of clinics in Omaha, has prepared this volume especially for general practitioners who have installed *x*-ray equipments.. The book is simplified by the assumption that all such practitioners use interupter transformers exclusively. It is also taken in part for granted that they will make use of Coolidge tubes. The technic for raying each region of the body is carefully described and illustrated. Serial photography, the use of the fluoroscope, and location of foreign bodies receive brief consideration. A considerable chapter is devoted to dark-room procedures. The chief section of the book—positions and exposures—appears practically in atlas form—photographs with explanatory text. The book seems to us to be admirably adapted to its purpose. It contains no roentgenograms because the author does not intend to go into interpretation.

THE SECRETION OF URINE. By ARTHUR R. CUSHING, M.A., M.D., LL.D., F.R.S., Professor of Pharmacology, University of London, University College (formerly of the University of Michigan, U.S.A.). With diagrams. Price $3. London and New York: Longmans, Green & Company, 1917

THIS book could have been christened "The Physiology of the Kidneys," for there is little reference to the secretion of urine by diseased kidneys. But as the author is a pharmacologist rather than a physiologist his title is very appropriate, because much of the subject matter relates to the modification of urinary secretion by drug action, which is also studied extensively in animal experiment. A few pages at the close of the work are given to albuminuria and nephritis. The volume should be of value for collateral study in physiology, pharmacology, biochemistry, diagnostic procedures in reference to kidney action, and in therapeutics, and should be indispensable to the student throughout his undegraduate course.

DENTAL MATERIA MEDICA AND THERAPEUTICS, with Special Reference to the Rational Application of Remedial Measures to Dental Diseases. A Text-Book for Students and Practitioners. By HERMANN PRINZ. A.M., D.D.S., M.D. Professor of Material Medica and Therapeutics, the Thomas W. Evans Museum and Dental Institute School of Dentistry, University of Pennsylvania, etc. Fifth Edition, Enlarged and Revised According to the United States Pharmacopeia, Ninth Decennial Revision. Price $5. St. Louis: C. V. Mosby Company, 1917.

THE fourth edition of this well-known work, published in 1916, was exhausted within a year, and the author was enabled to incorporate in the present edition certain changes in the recent revision of the United States Pharmacopeia, some of which were recommended by the author in his capacity of chairman of the Committee of Revision of the Section on Stomatology of the American Medical Association. Other innovations comprise an Index of Drugs and a rewritten section on ionic medication. This edition has gained twenty pages and twenty illustrations. The principal new drugs dealt with are cotarnine hydrochloride, betaeucaine hydrochloride, paraformaldehyde, and sodium perborate.

PHYSICAL EXERCISES FOR INVALIDS AND CONVALESCENTS. By EDWARD H. OCHSNER, B.S., M.D., F.A.C.S., President Illinois State Charities Commission, Attending Surgeon Augustana Hospital, Chicago. Illustrated. Price 75 cents. St. Louis: C. V. Mosby Company, 1917.

THIS little work contains forty cuts, which illustrate as many kinds of free gymnastic exercises, with explanatory text. The exercises themselves are eminently simple and familiar, but as they are combined with deep breathing they acquire a new quality which makes them more akin to athletic sports and physical exertion in other directions. In the sedentary they can take the place of a certain amount of manual labor. The author quotes from William Penn to the effect that work is wholesome for the mind as well as for the body.

FOOD FOR THE SICK. A Manual for Physician and Patient. By SOLOMON STROUSE, M.D., Associate Attending Physician the Michael Reese Hospital, Professor of Medicine at the Post-Graduate School, Chicago. and Maude A. Perry Dietician at the Michael Reese Hospital, Chicago. Price $1.50. Philadelphia and London: W. B. Saunders Co., 1917.

THIS book is ostensibly written for the physician and patient, but the nurse is not mentioned, perhaps because she is pretty well supplied with text-books on feeding the sick. The authors plunge almost at once into the subject matter of the book, *i.e.* such sections as the chemistry of foods, digestion, etc., are very briefly outlined. The large amount of space often given to recipes in works of this kind is also greatly cut down. Ménus, as distinct from recipes, are well represented. Calory feeding iis not overdone; indeed some readers may think it slighted.

Society Reports.

AMERICAN ASSOCIATION OF OBSTETRICIANS AND GYNECOLOGISTS.

Thirtieth Annual Meeting Held at Newark, N. J., September 17, 18 and 19, 1917.

THE PRESIDENT, DR. JOHN W. KEEFE OF PROVIDENCE, RHODE ISLAND, IN THE CHAIR.

Fundal Hysterectomy to Reduce the Menstruating Surface.—Dr. GORDON K. DICKINSON of Jersey City, N. J., stated that all operations on the pelvis should be as conservative as operations upon the brain and upon the thyroid gland. Not only should there be a minimum amount of mutilation of tissue, but the least possible interference with the circulation, particularly of the sex glands. Prognosis and effect of such interference would depend largely upon the full development of the internal secretion and its effect upon the organs and tissues of the body. Climate and civilization apparently tended to a degeneration of that which developed the feminine. People from the older countries, where the call of the germ plasm was less restricted, gave us the best feminine development, and of them particularly surgeons should be most careful. Metritis was an effect of slow tedious confinement, relaxed uterus, and infection. Sometimes it was fibrofatty, sometimes cirrhotic, sometimes arterial fibrosis. It might tend to hyperplasia of the endometrium, or in the cirrhotic type, atrophy. In both there was a tendency to sterility and hemorrhages. The curette had been employed without benefit and, at times, with harm. Chloride of zinc might succeed in the hands of the most skillful. Radium was of great value, but it had its obvious restrictions. By fundal hysterectomy done through the vagina we had a procedure which was simple, safe, and effective. After placing a purse-string around the anus, so that during operation there might be no puffing out of the foul matter from that vent, a clip was applied to each labium, which was retracted open. Into the vagina was poured an ounce or more of 3½ per cent. tincture of iodine, which was allowed to remain while the patient was being draped. When everything was ready, a volsellum was put on the cervix and it was brought down. A transverse incision was made anterior to the cervix, bladder separated from the uterus, the peritoneal cavity was opened, and the fundus was very easily brought into the vagina. We now had an inspection of it and the adnexa. Clips were firmly but gently applied alongside the uterus to slightly compress the circulation and act as retractors. A V-shaped incision was then made through the substance of the womb for various depths, depending upon the extent of the disease as estimated by the clinical sign of hemorrhage. This was not made too close to the fornix because the object was not so much the reduction of the uterus as the reduction of the menstrual surface. After this wedge-shaped piece was removed, both fornices should be thoroughly cauterized. If not, they would respond at the menstrual period, and producing tension give rise to pain. The cervical portion should also be touched for aseptic reasons. The part removed was carefully inspected for any appearance of malignancy. With a small, sturdy, curved needle the two flaps were approximated, staunching hemorrhage. The peritoneal surface was further brought together by running catgut, the clips were removed, the uterus was pushed back into place, and the anterior colpotomy wound sutured.

Dr. ROBERT T. MORRIS of New York City said that our surgery, conservative or otherwise, must be moulded according to the individual woman, her age, her wishes with regard to children, her objection or otherwise to an incomplete operation, with the possibility of recurrence of the condition. All these things belonged to the individual woman. In considering the subject of decline, Dr. Dickinson did not make a clear distinction between nation and race. That we must keep clearly in mind. In this country there was a very rapid decline, and more rapid than in other countries, because in this nation we had not developed strong racial types. When nature limited the development of a race she struck at the female sex, first among plants and animals, and consequently we found a larger degree of forms of arrested development among the women than we did among men, and very few were 100 per cent. women. We found in the masculine type the pyramidal form of pubic hair. We found the short clavicle; we found the various changes which need not be enumerated here, but when the sexes approached each other in type, in anatomy and mentality, there was a tendency to represent the other sex in the course of decline. Decline did not mean that mentality might not be higher. Some of the most brilliant and most valuable members of society among women were those that were masculine. They were not the ones to breed, they ought not to breed; they had no business to breed, and we had no business to help them to do it. That was not their function. They represented a mental state which was tremendously valuable to society.

Dr. ALBERT GOLDSPOHN of Chicago stated that there was one feature about this surgery that some of his obstetric friends would rather object to from the standpoint that they objected to having the abdomen opened and the uterus cut into in order to find out what was the matter in it. In view of that, it was somewhat called for to allude to this that more efficient work could be done medically without operating to help some of these cases that were not extremely bad. The use of tincture of iodine applied to the endometrium, say about twice a month, in an effective manner, would convert many of these people into cases in which it was not thought necessary to operate. Chloride of zinc would be needed once in a while, and while it was destructive, it would easily do the work. If chloride of zinc was to be applied efficiently to the endomterium, the fundus, it was necessary to dilate the cervical canal with sounds the same as one would stretch a stricture of the urethra with a large-sized sound, but one with a lesser curve. The woman would need to have a good dose of morphine, or the cervical canal would be required to be anesthetized with carbolic acid or cocaine for this purpose. Ample dilatation to something like 20 or 24 French should be made first under a clean technique, then the application must be made with some kind of syringe applicator, wrapped with cotton and dipped into the liquid, introduced, and the cervical canal cauterized extensively, doing nothing to the fundus. The cervix must be covered with a swab or absorbent cotton. The air must be forced out, the cotton must be wet with some antiseptic, and then immediately such an ample dilatation the applicator with the chloride of zinc was introduced without any difficulty. Treatment of this kind did much more good than any mechanical curettement.

Dr. HUGO O. PANTZER of Indianapolis said that the principle of conservatism enunciated by Dr. Dickinson in connection with our work led him to call attention to the newest science of menstruation. In brief, we realized that the ovaries were not singly the cause of menstruation; that we had not only the hormone of the ovary but the hormone of the endometrium, and perhaps it might be suggested some time later that we might have a hormone of the breast to consider. To ablate the entire endometrium would inflict unnecessary violence upon the sexual function and upon the chemism of the entire body, and it was with great hesitancy that we acted in a radical way in these cases, using the cautery for the destruction of the endometrium, or doing what was only a partial affair, removing a part of the endometrium as suggested by the essayist. A new view to him was that coming from the effects of toxemia upon all glandular structures, either a toxemia by intestinal statis, or the infectious focus located in the tonsils, the posterior nares, the gums, the jaw, or elsewhere. The immediate effect of such toxemia upon the glands of the body spelled blight of these glandular organs.

Physical Conditions in Women Warranting Sterilization.—Dr. E. W. HEDGES of Plainfield, N. J., said that sterilization should never be lightly undertaken, but there were conditions in women not infrequently met with, when this operation would save lives that otherwise would be needlessly sacrificed. In such cases, after a consultation, one should proceed to resect the tubes. Where a woman had had eclampsia in two suc-

cessive labors we were not warranted in risking another conception. Where real diabetes existed—not the transient glycosuria of pregnancy—we should sterilize. Otherwise 50 per cent. of the mothers would perish before or shortly after labor and two-thirds of the babies would be lost. Chronic nephritis cases should never marry or conceive, but if they did both—or if the disease developed after marriage, then they should be sterilized. If conception had begun we should do an abdominal hysterectomy at the same time. Exactly the same rule applied to pulmonary tuberculosis. Both diseases were aggravated by pregnancy and a fatal termination hastened and practically all hopes of recovery removed. Women with marked heart decompensation should not conceive. The vast majority of the children in such cases died in abortion, premature labor, or stillbirth, and a third of the mothers needlessly lost their lives. In all the classes of cases so far mentioned the children, even if born alive, entered life with such a physical handicap that no well-wisher of the race could give them welcome, and the risk for the mother was so great that it should be prevented by sterilization. If seen first when pregnancy had commenced an abdominal hysterotomy and sterilization should be done at the same time. If the child was near viability an attempt might be made to tide the case over a short time and then bring on labor. As to pyosalpinx the old rule held good. If the woman was well to do, let her alone with a nurse and a fountain syringe and an easy chair. But if she had to earn her living take out her tubes and give her health and sterility. Certain cases of insanity, the feeble-minded, and idiots, as well as epileptics should be cared for in institutions, but if living at home the question of sterilization should be carefully considered.

Dr. Edward J. Ill of Newark, N. J., stated that Dr. Hedges had touched upon a very serious question which was going to be abused just as much as the removal of the uterus or the removal of the ovaries was. The sterilization of women was a perfectly legitimate and proper thing, but we must be exceedingly careful which cases we subjected to this operation. He thought we all agreed that the state had a perfect right to sterilize epileptics, the criminals, the insane, and the idiotic, whether males or females, it did not make any difference. We could also say that cases of repeated cesarean sections should be sterilized. He had performed cesarean section three times in succession within a couple of years. He thought that was the limit, so he sterilized this woman. When it came to cases of chronic nephritis, he was not quite sure that we had a right to sterilize such women. In these days of commercial crazy surgery, it was well worth while to set a limit to what we were going to do in this particular field.

Dr. Herman E. Hayd of Buffalo said that there was no question but what Dr. Hedges' invocation was beautiful and that we should seriously, reverently, and with the fear of God operate upon women, but, it seemed to him, that Dr. Hedges suggested an omniscience on part of the surgeon that did not exist in this mundane sphere. For him to assume that such and such a case of diabetes, or such and such a case of chronic nephritis was going to die was absurd; it was unscientific; it was too sweeping, and, moreover, that we should possess in the way of surgical qualifications such an infinity that we were going to be able to carry these people through this surgical undertaking without a mortality was equally absurd in his judgment and equally extravagant. He believed that sterilization would be justifiable in these cases of chronic nephritis and of diabetes, provided these women were about to die of some unrelieved condition, such as a perforating ulcer of the stomach, a duodenal ulcer, and acute gangrene of the gall-bladder, or an acute appendicitis.

Dr. Gordon K. Dickinson of Jersey City, N. J., said he had never had the courage to sterilize women except for narrow pelves, and where the children could not be born except by repeated cesarean sections. If we felt the necessity of saving a woman from pregnancy; if after carefully studying the woman as well as the condition, we thought it was wise to sterilize her, we should do so, but not until we tried other measures which were well known and which were not surgical.

Dr. Charles L. Bonifield of Cincinnati stated that there were certain conditions which had been mentioned which justified sterilization; but the doctor's enthusiasm had carried him beyond the sphere of a private physician. If the State in its wisdom made laws to prohibit marriage, or if the State in its wisdom made laws to necessitate the sterilization of certain women, in obeying these laws we would be considered good citizens. But to make a law for ourselves as broad as the doctor had laid down, he was free to confess that his conscience would not permit it. He did not believe it was within the province of the doctor in some of these conditions to place a woman so that she could not become pregnant. If she should not become pregnant, it was the physician's place to tell her and her husband so, and it was their business to say that she shall not become pregnant, and not ours.

Dr. Robert T. Morris of New York City said that Dr. Hedges' paper was all right, but it required elaboration. He would not think of sterilizing a woman for diabetes until he had spent $200 trying to find out the cause of her diabetes. We must remember that diabetes was not a disease but a symptom. In connection with what Dr. Hedges said about tuberculosis, more than 50 per cent. of the people in all the civilized world had had evidences of this disease of one sort or another during some stage of their lives. We had postmortem records to that effect. In tuberculosis of the lungs, advancing and uncontrolled, he would say yes, sterilize the woman.

Dr. William E. Darnall of Atlantic City, N. J., sympathized with Dr. Hedges and the knocks he had received. He did not believe he meant to say that women in every one of these various classes that he had enumerated should be sterilized, but he did believe there were cases in each one of these classes that should be sterilized After a thorough study of the case and elaboration of the whole make-up of the woman's constitution and her tendencies, perhaps there might be found in each class some women who needed to be sterilized.

Dr. Hedges, in closing, said that if a woman presented anasarca, rapid heart, dyspnea, and extreme symptoms of poisoning from chronic nephritis he would not hesitate to sterilize her. He purposely omitted the milder cases of chronic nephritis which might go through. When the textbooks told us that thirty per cent. or more of mothers that became pregnant under conditions of chronic nephritis died, when otherwise they would not die, we were warranted in advocating sterilization of such women.

Demonstration of the Operation for the Cure of Complete Perineal Laceration.—Dr. Edward J. Ill of Newark, N. J., stated that in performing this operation he made an H-shaped incision which extended from just inside Bartholini's duct down to, to the outer side of, and behind the ends of the sphincter. The horizontal bar of the H started above the end of the sphincter and continued across the vagino-rectal junction. The anterior and posterior flaps were elevated, particular care being exercised to denude the ends of the sphincter. Submucous suture of the rectum by a double line of fine plain catgut was resorted to. The catgut never touched the rectal mucous membrane. Deep silver wire perineal sutures were used and the vagina was sutured with plain catgut.

Prolapse of the Uterus.—Dr. Charles L. Bonifield of Cincinnati said that recognizing how and why prolapse had occurred, the rational treatment was to decrease the weight of the uterus, replace it in its normal location and attitude and relieve it of all its abnormal burdens. The weight of the uterus might be decreased by rest in bed, curettage and amputation of the cervix, which was always hypertrophied in these cases. The uterus might be held in its normal place and attitude by a Gilliam operation, or if the patient be passed the child-bearing period, a ventral suspension, which was a little more easily and quickly done, and the uterus might be relieved of other burdens by the proper operations on the posterior vaginal wall and perineum and the anterior vaginal wall. Some surgeons did not like to take the time necessary to perform the surgical steps that resulted in an anatomical and physiological cure of

these cases. If the operator was determined to be very deliberate about his work, there was no reason why the operation should not be divided into two steps. He maintained that it was better to restore a woman to her normal condition by an operation that required time and care for its execution, than to mutilate her with one that seemed more brilliant and could be done in less time.

Operative Treatment of Procidentia.—Dr. ARTHUR T. JONES of Providence, R. I., said that numerous operations had been devised from time to time for the condition of procidentia, but few of these had been satisfactory and had given us the desired results. In the selection of an operation the age of the patient was one of the first things to be taken into consideration. If the woman was still in the child-bearing period and capable of becoming pregnant, it might be wise to choose a different operation from that we might choose in the woman who had passed the menopause. No operation which did not permit of pregnancy and the patient carrying her child to term should be performed upon a woman still within the child-bearing age. Hysterectomy should not be performed on a woman still in the child-bearing period, unless there were other indications than the mere presence of procidentia. If it was necessary to remove the uterus, the vagina and cervical stump might be suspended with the round and broad ligaments which, in connection with proper vaginal and perineal work, would prevent further prolapsing of the vagina and cervix. No operation for procidentia was satisfactory which did not include the proper vaginal and perineal work, as support was needed below in conjunction with any suspension or interposition operation. In women still within the child-bearing period, without complications or disease of the appendages, the Alexander operation in connection with proper vaginal work had been very satisfactory in his hands. In women past the menopause the interposition operation of Watkins-Wertheim had been the operation that had given greater satisfaction than any other method of treating this distressing condition.

Cervical Lacerations; Their Significance for the Patient.—Dr. FRANCIS REDER of St. Louis said that a cervical laceration of the uterus invited infection like any other trauma. The anatomical position of the cervix and the vaginal secretion with its bacterial defenses, were potential factors in frequently preventing an infection of a high degree. Cervical lacerations in a surgical sense must be considered portals of entry for infection. Such an infection might manifest itself in disturbed function of the uterus, tubes and ovaries, and, as a consequence, might cause in a woman having an unstable nervous organization a great loss of nerve tone. The immediate repair of a torn cervix was, as a rule, not permissable on account of its deformed and edematous condition. However, a cervical laceration six to eight weeks after accouchement, when the tissues had assumed quite their normal characteristics, was a trauma which should receive surgical attention, especially when the tear was lateral and extended into the zone of vaginal attachment. Gynecological and neurological sequelæ from this source were then avoided. The technique was simple. No general anesthetic was necessary, no special aftertreatment was required, and forty-eight hours of absolute quiet was all that was asked of the patient.

Acute Dilatation of the Uterus.—Dr. N. STONE SCOTT of Cleveland, Ohio, said that a review of the literature gave the impression that acute dilatation of the uterus was of frequent occurrence or of little more than didactic importance. A study of the six cases which formed the basis of his paper had brought him to the conclusion that acute dilatation was not rare and had furnished an explanation of this apparent scarcity. From a careful study of his own cases, and those of others, he had come to the following conclusions in his own mind. He realized that the number was too small and the territory traveled too new to furnish a basis for dogmatic assertions. Acute dilatation during the early months of pregnancy presented a marked difference from acute dilatation at term, in that it had no appreciable influence upon the bleeding. The more or less complete hemostasis occurring after the complete separation of the placenta after an ordinary miscarriage depended upon the hemostatic properties of the blood and blood vessels and this was not materially modified by an acute dilatation. A uterus at full term, which had been emptied of its contents, would have an alarming hemorrhage if it did not contract and control the bleeding by muscular action. This was due to the changes in the blood vessels which had taken place during the pregnancy. Should a contracted uterus lose its muscular tone and again dilate the same alarming hemorrhage would supervene. Some authors believed that acute dilatation was a phenomenon of sepsis. Maier thought that acute dilatation would only occur when there had been a prior disease of the muscle wall. The cases reported today bore out the theory that the disease must be in the uterine cornua, where interference with the uterine innervation would be most marked. Three of his cases had a placental implantation in one or the other horn, and the fourth had a small fibroid in the same place. Among the cases reported, great dilatation occurred only in those which had been recently pregnant.

Dr. HUGO O. PANTZER of Indianapolis, in confirmation of the doctor's observations, wished to report briefly a case occurring in his practice within the last seven weeks. The woman was 38 years of age, who was operated on for appendicitis, who had had continuous bleeding for six weeks. She had been married many years, but was never before pregnant. The breast changes were indifferent; a diagnosis of pregnancy was doubtful. A fibroid tumor as a possibility was entertained. On dilating the uterus he found a phenomenon described by the essayist and for a moment was in doubt as to whether he had perforated the uterus or not, and then with instrument he felt a perfectly intact wall, as he thought. He opened the abdomen from above and found the uterus relatively small and not perforated. He removed the fetus through the opening made in the uterus.

Dr. EDWARD J. ILL of Newark, N. J. had heard of this thing happening a number of times, but he had never seen it. What he had seen, when he thought he had that sort of thing, was that the curette or sound was passed through below the os internum, low down, through the posterior wall of the uterus into the peritoneal cavity. He rather thought in Dr. Pantzer's case there was a perforation of the uterus low down behind or at either side. He had seen a crochet needle go into the cellular tissue behind the uterus.

DR. WILLIAM H. HUMISTON of Cleveland, Ohio, said that in a case he was demonstrating to the class, the woman having had several attacks of appendicitis and had one then, abortion took place. He told the students how easy it was to perforate the uterus and how careful one should be. He took his dull curette, introduced it, and it kept going in without any effort. He found he had perforated the uterus after having told the students how to avoid it. He removed the placental tissue and opened the abdomen. Sure enough, there was a puncture in the posterior uterine wall. He removed the appendix, sewed up the hole in the uterus, cleaned out a few clots in the pelvis and she got well.

Dr. WILLIAM E. DARNALL of Atlantic City, N. J., said that we all had punctured the uterus, and we knew that we could do it very easily, but what Dr. Humiston said did not explain why a uterus that was three and a half or four inches deep suddenly became six inches deep.

Dr. JAMES E. DAVIS of Detroit wished to call attention to two or three points. When a muscle was stimulated with the electric current, for instance, the muscle bellied out. If we continued the application of the electric current until extreme irritation was reached, then the muscle would lengthen. Coupling that with the condition which Young had recently called attention to in regard to the enzymes or hormones that were produced by the epithelium of the chorion in pregnancy, which brought about a marked condition of edema in early pregnancy, it seemed we had two conditions which might explain what we had taking place. The epithelium of the chorionic villi threw out during the first three or four months of pregnancy, according to Young, who studied this question carefully from 75 histological sections, an enzyme which had the effect of producing first edema, and later on marked dilatation of the blood vessels. This edema might be so marked as to extend

throughout the entire body, making that condition which all of us had clinically taken to be some error in the kidney condition, but it had really been due to the enzymes produced by the trophoderm layer of the chorion.

Dr. J. Henry Carstens of Detroit said that we had a uterus that was firm, but as a result of profound anesthesia there was relaxation of the muscles. It was not such a dilatation as we got in the heart muscle, but it was simply a relaxation, and the muscles became flabby, and when you introduced a sound into the uterus, and the muscles had not undergone fatty degeneration or an edematous condition, you simply shoved the uterus away up and it seemed ballooned when it was not. The uterus was of normal size, except its walls were thin.

Dr. Scott, in closing, stated that the question of the anesthetic causing this dilatation of the uterus could be excluded.

Dr. Van Amber Brown of Detroit asked Dr. Scott if in any of his cases there was a marked anemia that antedated the pregnancy? That had been given as one cause of dilatation of the uterus.

Dr. Scott, in replying to Dr. Brown, said that he would not say that there was not any of them that had anemia, but some of them did not have bleeding of sufficient moment to produce anemia. Some of them were young women who were in a healthy condition and were not anemic.

Carcinoma Occurring in the Stump of the Cervix Following Suprapubic Hysterectomy.—Dr. Edgar A. Vander Veer of Albany, N. Y., stated that carcinoma of the cervix did occur in a few cases following suprapubic hysterectomy. Because it did so, it was not a point in favor of a panhysterectomy exclusively. The dangers of a panhysterectomy were greater than the risk of a carcinoma occurring secondarily in the cervical stump and being promptly treated. A careful examination should be made of every cervix before the hysterectomy was performed, particularly in women who had borne children. In every case of hysterectomy the patient should be advised to report promptly if there was any appearance of a vaginal discharge, a curettement done and a laboratory examination made. Removal of the cervix per vaginam was certainly to be preferred to opening the abdomen in every case where the disease had not progressed too far, as well as in cases having any discharge. All cases of this condition should be reported. Routine pathological examination of the myomatous uterus at the time of operation should be done, and in this way unsuspected cases of carcinoma of the uterus, also of the cervix, would be discovered, and the proper operation then performed.

Recurrences After the Five-Year Period in Carcinoma of the Cervix.—Dr. X. O. Werder of Pittsburgh stated that recurrences five to eleven years after operation had been reported from time to time from various sources. Most of these, however, had followed the older methods of operative treatment. The most important recent report of late recurrences had been furnished by the Wertheim Clinic through Weibel, whose investigation had shown in 185 cases surviving the five-year period 13 recurrences, or 7 per cent. In 59 cases of cancer of the cervix, operated upon by the radical cautery operation, he had 27 cases, or 45.76 per cent. living at the end of five years. In eight of these cases, or 29 per cent., recurrences were reported from five to nine years after operation. While the five-year recoveries after the cautery operation, therefore, showed better results than those of Wertheim, who was credited with 42½ per cent. of cures, the late results after five years were decidedly less favorable. The great difference in the percentage of late recurrences following these two methods of radical operation of carcinoma of the cervix was explained by the more unfavorable material dealt with as compared with that at the large European clinics. Late recurrences practically all developed in the glandular structures in which metastasis must have existed at the time of operation. It had been demonstrated that these might remain quiescent for years before active development took place. The greater frequency of late recurrences following the cautery operation must, therefore, be accounted for by a larger portion of lymphatic involvement, due to a more advanced stage of the disease at the time of operation. As only a small proportion of the regional glands liable to become invaded from the original cancer focus could be extirpated, this procedure was not considered as of any material influence in reducing the percentage of late recurrences. On the other hand, it might be argued that an agent which caused cancer metastases to remain dormant for so many years in such a large percentage of cases must have had some specific effect on the cancer cells, not present in the other operative procedures. It seemed possible that some product resulted from the intense heat in contact with living tissues which, while not absolutely destructive, rendered the cancer elements harmless—in many cases for years.

Dr. J. Henry Carstens of Detroit said that he had been fortunate enough in that he had never had a case of cancer of the cervix in any of his suprapubic hysterectomies. He recalled one patient who had a discharge and some irritation of the cervix. He took her uterus out per vaginam, had it examined carefully, and there was nothing malignant about it.

Dr. Edward A. Weiss of Pittsburgh stated that in 1898 Dr. Werder described the so-called combined operation for cancer of the cervix. He performed this operation and described it. Two years later Wertheim described identically the same operation. When Wertheim's attention was called to this fact he gave Dr. Werder priority, but in none of his subsequent writings had he given Werder credit for the operation. Dr. Werder was not satisfied with the results of this operation because the mortality was high and the morbidity very great. Twelve years ago he began to do what he now called igni-extirpation, and his results had been remarkable as compared with those from the old operation, both as to mortality and morbidity.

Dr. Werder, in closing, said that during the last two or three years he had had four cases in which he found carcinoma in the cervix, following the removal of the uterus some time previously. In most cases hysterectomy for fibroid antedated the operation for cancer of the cervix for a number of years, so that he was beginning to consider the removal of the cervix in cases of fibroid of the uterus, and where he did suprapubic hysterectomy he opened the uterus and inspected its cavity to see whether there was any evidence of carcinoma. In several instances he had found carcinoma present in the body of the uterus, and it was also advisable to do a preliminary curettement to be absolutely sure of the condition of the cervix. With those precautions we could safely continue to do suprapubic hysterectomy, which was far superior to a panhysterectomy, not even considering the fact that it was accompanied by a less mortality.

Radium; Further Clinical Observations.—Dr. Douglas C. Moriarta of Saratoga Springs, N. Y., stated that radium, as a therapeutic agent in certain cancerous conditions, had not received the consideration to which it was entitled, either as an adjunct to surgery when all the infected tissues were not or could not be removed, or as a palliative measure in inoperable cases. In a case of cancer of the rectum, the rectum and sphincters became functionless, and after the use of radium they functionated again. While this patient lived only a few months, the relief of the condition was a source of comfort to the patient and his family. While clinicians and physicists only conceded the gamma rays to be active at a distance of from three to five centimeters from the points of application, and claimed that beyond this distance they would stimulate the growth, he personally questioned the accuracy of their conclusions, believing that the distance at which the gamma rays acted might be influenced or stopped in some manner by the individual infection, or peculiar resistance of the tissues, and he would quote briefly two cases to justify this conclusion.

The first was a case of procidentia in which the uterus was four by six inches in size, with the cervix everted so that it had the appearance of a large cauliflower, five inches in diameter. Radium was applied, the growth relieved, the cervix resumed its normal contour, and the uterus diminished in size and receded to its normal position in the pelvis.

The other case was that of a negress, 46 years old, who had a fibroid of six years' duration, undergoing cancerous degeneration. It filled completely the abdominal cavity and extended to the ensiform process.

Radium was used, and now, after five months, the growth was about four inches in diameter and movable. The distance from the point of application of the radium in the first instance was from 12 to 15 centimeters, and in the latter case about 30 centimeters.

Mixed Cell Tumor of the Kidney Weighing Three Pounds in an Infant Ten Months Old.—Dr. WILLIAM E. DARNALL of Atlantic City, N. J., said that these tumors were considered malignant, but might be benign. Whether they were to be classed with carcinomas or sarcomas seemed to be a question pathologists had never definitely decided. Metastases were late, but eventually occurred. The adrenal tumor might arise from adrenal rests in ectopic portions of kidney, ovary, testicle, liver, mesentery, lungs, or bones. A review of the current literature of the reports of similar tumors to this one showed a hopeless failure to arrive at any adequate classification. Until the etiology was more definitely known no classification would be satisfactory. These tumors were always made up of mixed cells. Each pathologist seemed to have named the type of tumor according to the tissue cells he might have observed in the microscopic examination. The same pathologist would no doubt find many varying types of cells in different portions of the same tumor, and it was therefore necessary to examine every part of the tumor or some of its elements would be overlooked. The term hypernephroma had for convnience sake been applied to them, but hypernephroma might mean almost anything that was a kidney tumor. The immediate mortality from operation was high, but with improved technic it was lowered. Recurrences were said to take place in from 70 to 80 per cent. of the cases. Early diagnosis and operation are the only hope of saving more of these cases. A large percentage of them developed metastases and died. Some, however, had remained well after the removal of the tumor. More favorable results might be obtained, no doubt, if the cases could be discovered and operated upon earlier.

Dr. JAMES E. DAVIS of Detroit stated that the stigmata of arrested development were, from a pathological standpoint, very much neglected, and if we had more thorough pathological examinations of postmorten material, he was sure more cases of this particular type would be discovered. It was not an uncommon thing to find in the genitourinary system or the generative system, or in the kidney, embryonal rests which might for some unknown reason remain for years and years, did no harm whatsoever, but all at once some condition in the metabolism caused these rests to begin to grow very rapidly, and he was sure that pathologists had found a considerable number of these cases in very young children.

Dr. E. GUSTAV ZINKE of Cincinnati said that he had been engaged in the practice of medicine for nearly half a century and had gone through the various periods of theoretical hypotheses with reference to the origin of malignant growths, and every now and then, as he had today, he was vividly reminded of a theory of the occurrence of cancer that had been more or less abandoned, and that was, that all cancers were really of embryonal origin. Some of these embryonal cells became shut off from the rest; they went to sleep, as it were; they remained inactive and inert for years, and sometimes, as the result of an accident, a fall or a blow, or something of that kind, or in consequence of some irritation, they were reawakened, they became active, and the result was a malignant growth.

Dr. GORDON K. DICKINSON of Jersey City, N. J., said that as to the theory of cancer being produced by repeated irritation, Dr. Carstens very forcibly brought out at the meeting of the Association, a year or two ago, the fact that we might have many severe continued irritations, yet without producing carcinoma. The theory of Cohnheim that cancer was of embryonal origin appealed very strongly to him, consequently, in the near future it might be pointed out as one of the truths which would be proven to be the cause of some kinds of cancer. Irritation, traumatism, might enter the field for another type of carcinoma, and the chemical factor.

Gall-Bladder Trouble Complicating Disease of the Internal Genitals.—Dr. J. HENRY CARSTENS of Detroit stated that we frankly found gallstones connected with pelvic trouble, especially firboid tumors, pelvic adhesions, and displacements. It was claimed that five women had gallstones to one man. If we inquired into the history of these women we would find that they often had had puerperal fever, septic conditions following labor, or miscarriages, and were confined to bed for four to six weeks. Even if no symptoms were complained of by the patient, we could usually by palpation detect gall-bladder trouble, and be prepared to relieve it when operating for the other trouble. To sum up, he would say: (1) Many women with pelvic trouble had also disease of the gall-bladder and upper abdomen. (2) No patient, with even simple pelvic disease, should be operated unless a perfect diagnosis had been made of all abdominal troubles, if that was possible. (3) In cases of doubt, the incision should be large enough so that the whole abdomen could be explored. (4) In all pelvic operations, where gall-bladder disease existed, the latter should be operated at the same time, provided that the patient's life was not in danger by prolonging the operation.

Gall-Bladder Surgery.—Dr. JOSEPH H. BRANHAM of Baltimore said that the medical treatment of gall-bladder disease was of great importance. Although we knew that the removal of the gall-bladder was not followed by very serious conditions, and that drainage was not a dangerous procedure, yet our studies indicated that the gall-bladder had certain functions, and drainage always caused a certain amount of damage to this organ. The adhesions which followed an operation were a source of pain and inconvenience, and, therefore, operative procedure should not be resorted to until proper medical and hygienic treatment had proved ineffectual. Such treatment generally consisted of proper diet, remedies to keep the flow of bile free, and as near as possible normal, and more especially such a course of exercise as would restore the tone of the abdominal muscles and, if possible, the normal contour of the abdomen. The surgical treatment of gall-bladder disease was of recent development. The relative advisability of cholecystostomy and cholecystectomy had been discussed pro and con by hundreds of surgeons. The advantages of cholecystectomy were: (1) The number of permanent cures effected by it were greatly in excess of those effected by cholecystostomy. (2) Secondary operations were very rarely needed. (3) Malignant conditions were only to be detected by microscopic examinations, and not infrequently found upon removal of the gall-bladder, and thus the danger of malignant development was prevented. Cholecystectomy was also better where there were marked diseased conditions, such as irregularities of the mucosa, the presence of gallstones, fibrous thickening of the gall-bladder or stricture of the cystic duct, and because it did not leave in situ a diseased organ to cause future damage. But its greatest advantage was that it did away with the adhesions which always followed drainage and were a source of discomfort and danger.

(To be concluded.)

State Medical Licensing Boards.

STATE BOARD EXAMINATION QUESTIONS

TEXAS STATE BOARD OF MEDICAL EXAMINERS.

Austin, June 19, 20, 21, 1917.

(*Continued from page* 573.)

HISTOLOGY.

1. Describe synovial membrane and state where found.
2. Name the forms of muscle and state principal locations of each.
3. Give histological structure of male urethra.
4. Differentiate, histologically, blood and lymph.
5. Describe in brief the spleen.
6. Give structure of the gall-bladder.
7. Describe the prostate gland.
8. Draw a cross section of the sciatic nerve and name principal points.
9. Describe the structure of a long bone.
10. Describe the uterus histologically.

MEDICAL JURISPRUDENCE

1. What is an inquest? When is it necessary?
2. What is meant by "presumption of death"?
3. What is a privileged communication?
4. What three methods are used in examining blood stains?
5. Give signs of death from suffocation?
6. When does impotence or sterility constitute grounds for divorce proceedings?
7. What constitutes "live birth"?
8. When is abortion not a crime?
9. What legal test governs the practice of medicine with regard to malpractice?
10. Define pyromania.

BACTERIOLOGY.

1. Describe the process of producing diphtheria antitoxin.
2. Give the process of staining for the *Spirochæta pallida.*
3. Describe in detail the process of finding tubercle bacilli in a specimen of urine.
4. Give complete life cycle of *Plasmodium vivax.*
5. Give a brief classification of the pathogenic protozoa found in the human body and give example of each.
6. Name three pathogenic spirilla and give the morphology of one.
7. Explain the difference between active and passive immunity; illustrate by example how each may be acquired.
8. Describe *Bacillus anthracis* under the following heads: morphology, staining, cultural characters, pathogenicity, and manner of infection.
9. Define the following terms: germicide, antiseptic, asepsis, sterile, disinfectant.
10. How would you proceed to find the number of bacteria per cubic centimeter in water?

OBSTETRICS.

1. Give treatment in placenta prævia with frequent or profuse hemorrhage before viability of the child.
2. How would you treat post-partum hemorrhage?
3. Give some of the causes, diagnosis, and treatment of rupture of the uterus.
4. Give indications for cesarean section.
5. What is puerperal insanity?
6. How would you treat the after-coming head?
7. How would you apply the forceps in right occipito-posterior position?
8. Define eclampsia, hydramnios, spurious pregnancy, decidua vera.
9. What is the diagonal conjugate and how would you estimate the true conjugate from it?
10. Give Harris' method of dilating the cervix.

ANSWERS.

HISTOLOGY.

1. A synovial membrane is composed of fibrous tissue, with an imperfect covering of cells on its free surface. These cells are gathered into little patches, are branched and irregular in shape, and are known as epitheliod cells. In some places there are long villus-like projections, which are covered by small round cells. There are numerous blood vessels in synovial membranes. These membranes are found in joints, in places where the tendons of muscles run over bones, and also between parts which move upon each other (such as two muscles, two tendons, skin and a bone, tendon and bone).

2. The types of muscle tissue are voluntary and involuntary: also cardiac. The *voluntary* muscles are striped, are more or less under the control of the will, do not contract rhythmically, do not evince peristalsis, and the nerves to them end as "end-plates." The *involuntary* muscles are unstriped, are not under the control of the will, contract rhythmically, show peristalsis, and the nerves to them end as a "plexus." The cardiac muscle is the heart.

Voluntary muscle is found in all the skeletal muscles, pharynx, diaphragm, larynx, external ear, and eye. *Involuntary muscle* is found in the alimentary tract from the middle third of the esophagus to the anus, in the ducts of glands, in the trachea and bronchial tubes, within the eyeball, the internal urinary and genital systems, circulatory (except the heart) and lymphatic systems, and the capsules of some organs.

3. The *male urethra* is lined in the prostatic part by transitional, but elsewhere by columnar epithelium, except near its orifice, where the epithelium is stratified. The epithelium rests upon a vascular mucous membrane, and this again is supported by a coating of submucous tissue, containing two layers of plain muscular fiber—an inner longitudinal and an outer circular. Outside this again is a close plexus of small veins which is connected with, and may be said to form part of, the corpus spongiosum. The mucous membrane is beset with small mucous glands, simple and compound (glands of Littré). There are also a number of oblique recesses termed lacunæ.—(From Schaefer's *Essentials of Histology.*)

4. *Blood* contains plasma, erythrocytes, leucocytes, and platelets. *Lymph* contains plasma, leucocytes, blood platelets, fat, and thrombocytes.

5. "The *spleen* is invested by a thick capsule, consisting of a fibro-elastic tissue and a large proportion of visceral muscle fibres. The capsule sends trabeculæ into the interior of the organ. These are thick, and the nuclei of the muscle fibres in them stand out conspicuous in stained specimens. The bulk of the organ is deep red in color, and is called the spleen pulp. In the pulp are numerous whitish nodules, about the size of a pin's head. These nodules are composed of lymphoid tissue surrounding small arteries, and are called Malpighian corpuscles. The pulp consists of a network of fine fibers, with a number of flattened and branched cells situated on the fibres and at their crossings. In the spaces between the fibres are numerous red corpuscles, large lymphocytes, and other blood cells. Many of the red corpuscles undergo disintegration in the large lymphocytes, so that pigment, both intracellular and free, is present. An occasional giant cell of bone-marrow type is seen in the spleen pulp. The splenic artery breaks up at the hilus, and the branches pass into the interior of the organ along the trabeculæ. Passing away from the trabeculæ, their outer coat becomes surrounded at intervals by nodules of lymphoid tissue—the Malpighian corpuscles. Each corpuscle usually shows a germ center. The arteries open into capillaries, which, in turn, open into the interstices of the pulp. From the pulp spaces there open wide venous sinuses, which are encircled by fibres of the reticulum, and are lined by a very prominent endothelium. These sinuses open into the radicles of the splenic vein."—(*Aids to Histology.*)

6. "The *wall of the gall-bladder* consists of three coats, mucous, muscular, and serous. The mucous membrane is thrown into small folds or rugæ, which anastomose and give the mucous surface a reticular appearance. The epithelium is of the simple columnar variety, with nuclei situated at the basal ends of the cells. A few mucous glands are usually found in the stroma. The muscular coat consists of bundles of smooth muscle cells, which are disposed in a very irregular manner, and are separated by considerable fibrous tissue. A richly vascular layer just beneath the stroma is almost free from muscle and corresponds to a submucosa. It frequently contains small lymph nodules. The serous coat is a reflection of the peritoneum."—(Bailey's *Histology.*)

7. *Structure of prostate.* "The prostate is a compound tubulo-alveolar gland whose ducts open into the prostate portion of the urethra. Smooth muscle fibers not only surround the organ, but interlace radially toward its center, forming a network in whose meshes the glandular parts are located. Areolar tissue and blood-vessels accompany the muscle tissue. The alveoli of the glands are lined by simple columnal epithelium, which sometimes show two rows of nuclei. These alveoli contain a serous acid coagulum and usually oval laminated concretions called *prostatic bodies.* The latter are more numerous in old men. The numerous excretory ducts unite to form twelve to fifteen collecting tubes which open into the urethra, most of them into the *prostatic sinus.* These ducts are lined by simple columnar epithelium, except near their terminations, where it is transitional. The organ in front of the urethra is mostly smooth muscle tissue."—(Hill's *Histology.*)

8. The fibers that constitute the sciatic nerve are grouped into bundles called *funiculi*. Each funiculus is enclosed in a connective-tissue sheath, the *perineurium*, which sends septa, the *endoneurium*, in among the individual fibers. The whole nerve is enclosed in a firm connective-tissue sheath, the *epineurium*. Blood and lymph vessels accompany the connective-tissue elements and ramify through the nerve just as is the case in a muscle. Fat cells are also found in the connective tissue of the bundle.

9. A cross-section of a bone shows *Haversian canals;* around these the bone is arranged in rings or *lamellæ;* between these are spaces (*lacunæ*) in which are bone *corpuscles*. Each canal is connected with the lacunæ which are concentric with it, and the lacunæ with one another by means of fine canals (*canaliculi*) into which project processes of the bone corpuscles. A Haversian canal with its lamellæ, lacunæ, bone corpuscles, and canaliculi form a *Haversian system*. In a section of bone several of these systems may be seen, the spaces between them being occupied by *interstitial lamellæ*. Lamellæ which are on the surface of the bone, parallel with its circumference, are *circumferential lamellæ*. A longitudinal section of bone shows the Haversian canals to be what their name indicates, channels running through the bone. Their communications with one another are also seen. In each canal are an artery and a vein. If a piece of bone is treated with dilute nitric acid, so as to dissolve the lime salts which it contains, or by some other method of *decalcification*, a small portion may be torn off, which upon examination shows the fibrous structure of the lamellæ. Such specimens also show the *perforating fibers of Sharpey*, which hold the lamellæ together; elastic fibers may also be observed.—(Raymond's *Physiology.*)

10. "The *wall of the uterus* is formed of the following layers: (1) A serous layer, derived from the peritoneum, which covers the greater part of the fundus. (2) A muscular layer, which is of considerable thickness, and is formed of plain muscular fibers disposed in two strata. Of these the outer has its fibers arranged partly longitudinally, partly circularly. The inner muscular layer is thick, and its fibers run in different directions, but chiefly circularly, and it is prolonged internally into the deeper part of the mucous membrane, the extremities of the uterine glands extending between and amongst its fibers. It is imperfectly separated from the thinner external layer by the ramifications of the larger blood vessels, and according to some authorities represents a much hypertrophied muscularis mucosæ. (3) A mucous membrane, which is very thick and is composed of soft connective tissue containing a large number of spindle-shaped cells. It contains long, simple, tubular glands, which take a curved or convoluted course in passing through the membrane. They are lined by ciliated epithelium continuous with that which covers the inner surface of the mucous membrane. In the cervix the mucous membrane is marked by longitudinal and oblique ridges, and the glands are shorter than those of the body of the uterus. Near the os uteri the epithelium becomes stratified and overlies vascular papillæ of the corium. The mucous membrane is exceedingly vascular, and it also contains a large number of lymphatic vessels."—(Schäfer's *Histology.*)

MEDICAL JURISPRUDENCE.

1. An inquest is an inquiry made into the cause of death. It is generally made by a coroner with the assistance of a jury. It is necessary when there is a doubt as to the cause of death, when death occurs suddenly or under suspicious circumstances, and in unknown or unexplained cases of violent or sudden death.

2. *Presumption of death.* "In a general way it is held usually that if a person, having no material reason for disappearing or absconding, having family, friends, or business relations, who might reasonably be expected to know as to his whereabouts, is not heard from or known to have been living within seven years, the presumption of death is a reasonable one. In some cases, however, the law does not demand a lack of any knowledge for so long a period, and cases have been closed within two years after the disappearance. The circumstances associated with the disappearance frequently control the decision. If a person under suspicion or conviction of crime, in business or any family difficulties, disappears, a much more extended time would be necessary to establish this presumption."—(Dwight's *Epitome of Medical Jurisprudence.*)

3. *Privileged communications.* "In some States certain information acquired in the performance of professional duties is deemed privileged—that is, the physician cannot be compelled in court, in fact, may not be allowed, to disclose such information without the consent of the individual from whom it was so obtained. Under this ruling, information obtained by medical men in their professional capacity is held in the same light as information obtained by the clergy in the confessional or by the attorney from his client. In other states no privileges are granted the physician, and he may be compelled against his wish and the wishes of his patient to testify to any knowledge, however obtained, which he may have. In those states where such communications are not recognized as privileged such testimony cannot be considered as a breach of confidence, and under the orders of the court it should be given freely no mater how distasteful to the witness it may be."—(Dwight's *Medical Jurisprudence.*)

4. *To identify blood stains:* (1) Some of the material from the suspected stain is thoroughly mixed with a few drops of a saturated solution of sodium chloride, and then allowed to evaporate to dryness on a slide covered with a cover-glass. Now add a drop of glacial acetic acid to the slide, and allow it to enter under the cover slip; then apply gentle warmth. If the suspected stain is *blood*, crystals of hemin will form later, and can be seen under the microscope.

Other tests are: (2) The demonstration of the *corpuscles* by the aid of the *microscope;* (3) *spectroscopic* appearance of two dark absorption bands in the green rays, and at the junction of the green and yellow rays; (4) *chemical* tests, and as the action of guaiacum and ozonic ether, nitric acid, or caustic potash.

5. *Signs of death from suffocation:* "Lividity and swelling of the face and lips are usual, but in accidental cases the face may be placid; the eyes are congested; minute ecchymoses appear on the neck and chest; with mucous froth, sometimes bloody, about the mouth and nose; the lungs and right side of the heart may be gorged with dark blood; but in some cases, especially in young children, the lungs may be empty of blood and emphysematous. Hence, the condition of the lungs and heart, as it varies so much, cannot be relied on in diagnosis. Stress has been laid upon the presence of minute punctiform ecchymoses, especially on the lungs of newborn infants who have been suffocated. These spots are also found on the pleura, lining membrane of the heart, membranes of the brain, peritoneum, and mucous lining of the windpipe, but their value is not universally acknowledged. The blood is dark and very fluid. The kidneys are deeply congested."—(Reese's *Medical Jurisprudence.*)

6. Impotence or sterility gives grounds for divorce proceedings when the incapacity for sexual intercourse existed at and before marriage, when such incapacity is incurable, when the condition was known to the party suffering from it, and when too long a time has not elapsed between the discovery of the condition and the beginning of the divorce proceedings.

7. To constitute a "live birth," there must be (1) complete extrusion of the child from its mother's body, and (2) some certain sign of life. The latter would be established by one or more of the following: pulsation of the cord, beating of the child's heart, motions of the limbs, twitchings of the muscles, wrinkling of the brows, puckering of the face, opening of the eyes, even if respiration does not take place.—(From Witthaus and Becker's *Medical Jurisprudence*, etc.)

8. When abortion is undertaken by properly qualified physicians after due consultation with other physicians, and for the purpose of saving the life or health of the mother, it is *justifiable;* under all other circumstances it is *criminal*. The former is a perfectly lawful medical procedure; the latter is illegal.

9. *Malpractice* is a failure on the part of a medical practitioner to use such skill, care, and judgment in the treatment of a patient as the law requires; and thereby the patient suffers damage. If due to negligence only, it is *civil* malpractice. But if done deliberately, or wrongfully, or if gross carelessness or neg-

lect have been shown, or if some illegal operation (such as criminal abortion) be performed, it is *criminal malpractice.*

10. *Pyromania* is that form of monomania in which a person sets fire to buildings and other objects, for the mere delight of seeing them burn.

BACTERIOLOGY.

1. "Diphtheria antitoxin is obtained from the horse, the animal having been rendered artificially immune by repeated injections extending over a period of several months of gradually increasing quantities of the strongest diphtheria toxin. As the bacilli themselves are not injected, the horse does not become infected with diphtheria, but he gradually acquires a tolerance for the toxins of the disease and develops in his blood a substance (antitoxin) which has the power to neutralize those toxins. At the proper time, when it is thought that his blood has acquired the requisite degree of potency, the animal is bled, and the serum—the part of the blood containing the antitoxin—is carefully separated from the clot, filtered, and standardized. The last procedure is accomplished by determining the quantity of antitoxin serum required to offset the effects of the minimum quantity of toxin necessary to kill a guinea-pig in a definite time. The strength of the antitoxin is measured in units, a unit containing the amount of antitoxin required to save the life of a guinea-pig which has been injected with 100 fatal doses of toxin."—(Stevens, *Materia Medica.*)

2. *Process of staining for the Spirochæta pallida.* "Giemsa's stain is probably the most widely used. It is best purchased ready prepared. Smears are fixed in absolute alcohol for fifteen minutes. Ten drops of the stain are added to 10 c.c. of faintly alkaline distilled water (1 drop of a 1 per cent. solution of potassium carbonate to 10 c.c. of the water), and the fixed smear is immersed in this diluted stain for one to three hours or longer. It is then rinsed in distilled water, dried, and mounted. In well-stained specimens *Spirochæta pallida* is reddish; most other microorganisms, bluish. More intense staining may be obtained by gently warming the stain."—(Todd's *Clinical Diagnosis.*)

3. *To find tubercle bacilli in the urine:* "Withdraw the urine by a sterile catheter into a sterile conical urine glass. The urine so withdrawn is allowed to stand until the sediment collects. The supernatant fluid is poured off and the sediment is centrifuged. The supernatant fluid is poured out of the centrifuge tube, the tube is filled with distilled water that is free from tubercle bacilli, shaken so as to wash out the urinary salts, which interfere with the staining, and centrifuged again. This process is repeated once or twice. The sediment remaining after the third centrifugation is smeared on clean glass slides and allowed to dry in the air. The smears are fixed by passing three times through the flame, and then stained for five minutes with warm carbolfuchsin, washed in water, submitted to the action of the acid-alcohol solution for one minute, washed in water, counterstained with Löffler's alkaline methylene-blue for thirty seconds, dried, and examined under a 1/12-inch oil immersion objective. If acid-fast bacilli are found by this method, a second smear should be decolorized in the acid solution overnight, washed in water, and counterstained in the Löffler's alkaline methylene-blue in order to be sure that they are not smegma bacilli. Urine obtained by the catheterization of the ureters may be treated in the same way."—(Anders and Boston's *Medical Diagnosis.*)

4. *Life cycle of Plasmodium vivax.* This is a protozoan parasite, and is the organism of tertian malaria. In its earliest stage it appears within the red blood corpuscles as a colorless ameboid body, which grows rapidly, becomes pigmented, and when it has nearly filled the red corpuscle it undergoes segmentation, dividing into a rosette-shaped body containing some 15 to 20 spores. The corpuscle ruptures, and the spores are liberated and attack fresh corpuscles, and repeat the cycle of development, which lasts 48 hours. The above describes the asexual cycle; but some of the ameboid bodies do not become segmented, merely enlarging within the corpuscles to form rounded gametocytes, of which the male element is smaller than the female. When these are drawn into the stomach of the anopheles mosquito they burst the corpuscles, and the microgametocyte or male element puts forth three or four flagella, which become detached, and then penetrate and fertilize the female cell. This now becomes an elongated pointed body, which penetrates the mosquito's stomach wall, and develops on its outer surface into a capsule filled with thread-like exotospores. The capsule ruptures, and the exotospores are carried to the salivary gland and duct of the mosquito, entering the human blood at the insect's next bite, and there penetrating the red cells and becoming the colorless ameboid bodies.

5. *Classification of protozoa:* (1) *Sarcodina*, example Entemaba histolytica, causing dysentery. (2) *Mastigophora* or *Flagellata*, example *Treponema pallidum*, causing syphilis. (3) *Infusoria*, example *Balantidium coli.* (4) *Sporozoa*, example *Plasmodium vivax*, causing tertian malaria.

6. *Three pathogenic spirilla:* The spirillum of cholera, the spirillum of relapsing fever, and *Treponema pallidum* which causes syphilis.

The germ of syphilis is the *Treponema pallidum*, also called the *Spirochæta pallida.* It is a slender spirillum, with regular turns, the curves varying in number from three or four to twelve or even twenty; it is about 4 to 20 mikrons long, actively motile, with a fine flagellum at each pole; it is flexible, hard to stain, and has not been cultivated on artificial media. How it divides is not known. It stains best with Giemsa's eosin solution and azur.

7. *Immunity*, or the power to resist invasion by microorganisms with the subsequent development of disease, is *active* when the cells or tissues of the invaded individual bring about this immunity, either by destroying the bacteria or by neutralizing their poisonous products. Such an immunity may be acquired in several ways; one is by inoculation, another is by vaccination; this latter is used as a prophylactic measure against smallpox. Immunity is said to be *passive* when it is caused by the injection of the blood serum of an animal which has been actively immunized.

8. BACILLUS ANTHRACIS. *Morphology:* It is a large, rod-shaped microorganism, with slightly thickened ends; it is from 5 to 20 mikrons in length, and a little more than one mikron in breadth; it has a tendency to form long threads; it is nonmotile and nonflagellated; it is aërobic.

Staining: It stains by all the alkaline aniline dyes, and also by Gram's method.

Cultural characters: It grows on practically all media, as a film on potato, in tree form in gelatin stab, it liquefies gelatin and also serum.

Pathogenicity: It causes anthrax, splenic fever, malignant pustule, and woolsorter's disease. Infection takes place through wounds, or by the respiratory or alimentary tract. The bacilli are probably destroyed by the gastric juices, but not so the spores.

9. *Germicide* is an agent which destroys bacteria and their germs.

Antiseptic is a substance which prevents or restrains putrefaction.

Asepsis is the absence of pathogenic microorganisms.

Sterile is free from microorganisms or spores.

Disinfectant is an agent which restrains infectious diseases by destroying or removing their specific poisons.

10. "The standard medium for determining *the number of bacteria in water* is a nutrient agar having a reaction of +1 per cent., using phenolphthalein as an indicator. The agar is made by using distilled water and an infusion of fresh lean meat, and not meat extract. The medium contains 1 per cent. of Witte's peptone and 1 per cent. of agar. The sample of water must be shaken vigorously at least 25 times in order to break up the bacterial clusters and to obtain a uniform suspension. If the water contains less than 200 bacteria per c.c., 1 c.c. of it may be placed directly in the petri dish, then add 10 c.c. of the standard medium. Mix well, congeal, and incubate at 37° C. for 48 hours in a dark, well-ventilated incubator where the atmosphere is practically saturated with moisture. When gelatin is used the plates should be incubated at 20° C. for 4 days. If there is reason to believe that the number of bacteria is more than 200 per c.c., dilute by mixing 1 c.c. of the sample with 9 c.c. of sterilized tap or distilled water. Again shake 25 times and plate

1 c.c. of the dilution. . . . Count the colonies upon a Wolffluegel apparatus or a Jeffer's plate. A successful plate should contain not more than 200 colonies. The whole number of colonies on a plate should be counted, the practice of counting a fractional part being resorted to only in cases of necessity."—(Rosenau's *Preventive Medicine and Hygiene.*)

OBSTETRICS.

1. As a rule the pregnancy should be terminated when the hemorrhage is profuse and the fetus not yet viable; hence, empty the uterus.

2. *Treatment of postpartum hemorrhage:* Grasp the uterus at once, through the abdominal wall, and massage it firmly. Anything in the uterus should at once be cleaned out. Pass one hand into the uterus, and with the other on the outside make firm pressure. A hypodermic of ergotin or ergot can be given by an assistant. An intrauterine douche of hot sterilized water (about 115° F.) may be given. Sometimes a very thorough packing and plugging of gauze of uterus and vagina may be necessary. Whatever is done must be done promptly; and everything likely to be needed for this emergency should be prepared beforehand in every labor.

3. RUPTURE OF THE UTERUS. *Etiology:* Pathological conditions of the uterus, cicatricial tissue in the uterus, obstructed labor, contracted pelvis, malposition of the fetus, and violent operative procedures.

Ruptured uterus is announced by a sudden, acute, and persistent pain. Sometimes the sound of the rupture is heard by the patient; the symptoms of internal hemorrhage and shock are present—collapse, air-hunger, cyanosis, rapid, feeble pulse; the uterine contractions cease. Vaginal examination shows that the presenting part of the child has receded from its former situation owing to escape of the fetus (partially or completely) through the rent into the abdominal cavity, where it may be felt by abdominal palpation.

Treatment of rupture of the uterus: "After rupture has occurred, especially if it be 'complete' and extensive, and the child should have escaped, wholly or in great part, through the rent into the abdominal cavity, laparotomy should be done at once, child, placenta, blood clots, etc., being removed through the abdominal incision; then peritoneal cavity cleansed with hot saline solution; the rent in the uterus repaired by suture; or in case of an infected uterus, or one that will not contract, or in which the rupture cannot be well secured, the entire uterus should be removed."—(King's *Obstetrics.*)

4. *Cesarean section.*—"*Indications:* The cases in which it is performed are: (1) Extreme deformity of the pelvis, in which delivery by forceps and version is excluded, and in which craniotomy is either impossible or would be more dangerous to the mother than cutting into the abdomen and uterus; and in which there is not room for a successful symphyseotomy. Such cases present the '*positive*' indication for cesarean section; there is nothing else to be done. Flat pelves having a conjugata vera of 2¼ inches or less, and justo-minor pelves with a conjugata vera of 2½ inches or less, present this positive indication; (2) cases of more moderate pelvic contraction in which craniotomy is possible; but cesarean section is agreed upon to *save the life of the child;* (3) mechanical obstruction in the pelvis from fibroid, cancerous, bony, or other tumors which cannot be pushed up out of the way or be safely removed; (4) irreducible impaction of a *living* child in transverse presentations; (5) in women dying near the end of pregnancy the child, if alive, is rapidly delivered by *post-mortem* cesarean section; (6) various other obstructions from inflammatory adhesions, atresia, constrictions, etc., of the vagina, and uterine displacements, may rarely require the operation; (7) recently the operation has been done in eclampsia cases, where more conservative methods of rapid delivery were impracticable; and (8) in placenta prævia, chiefly with a view to lessen the infant mortality atttending the usual treatment of this complication."—(King's *Obstetrics.*)

5. *Puerperal insanity:* Heredity and personal predisposition, exhausting and debilitating conditions, postpartum hemorrhage, excessive lactation, intoxications, primiparity, mental distress, and septic infection are generally given as the etiological factors. The condition generally comes on early, in the first week; it is of a maniacal type, and may be suicidal or infanticidal; persistent insomnia is said to be a precursor of this insanity; when menstruation returns the condition often improves. Puerperal insanity is to be distinguished from lactational insanity; this latter generally comes on later, about the fourth month, and is apt to be of a depressed and melancholic type.

6. *Extraction of the after-coming head:* "If the arms are extended by the side of the child's head, they should be delivered first. The posterior arm is located by the position of the trunk and shoulders. To deliver the right arm, the child's ankles should be grasped with the left hand, and the body raised upward and outward over the mother's right thigh. The fingers of the right hand are passed along the posterior surface of the arm beyond the elbow. The fingers are hooked in the elbow, and traction is exerted; the forearm is then delivered by extension. The left arm is delivered in a similar manner. In the *Wiegand-Martin method* extraction of the after-coming head is effected by the insertion of the index finger of the supinated right hand into the child's mouth and making traction upon it, while pressure is exerted through the abdominal wall by the left hand. In the *Mauriceau* or *Veit-Smellie method,* in addition to the right hand index finger in the mouth, the left hand is also introduced into the vagina, along the back of the child, the middle finger presses against the occiput, while the remaining fingers exert traction over the clavicles. In the *Prague method* the child's ankles are grasped in the right hand, the fingers of the left are flexed over the clavicles, and traction is made. In these methods, when the perineum is distended, the child's body is raised toward the mother's abdomen. *Forceps* may be applied after the child's body has been raised and traction made in the direction of the axis of the parturient canal."—(*Pocket Cyclopedia.*)

7. *Forceps in occipito-posterior positions:* "The blades are put in exactly as for cases where the occiput has rotated anteriorly. But since the occiput is now toward the sacrum, the *extension will, of course, be downward and backward over the perineum,* instead of upward toward the pubes; hence the handles of the instrument, at first lifted somewhat upward toward the pubes to draw the occiput up to the edge of the perineum, must, when the head emerges, be directed *downward and backward,* instead of toward the *mons veneris.* A moment's reflection will show that the short *straight* forceps (without any sacral curves) should be used in these cases; for the said curve is only adapted to follow the axis of the pelvic canal, but during *backward* extension of the occiput over the perineum the head departs from the axial line and goes in an almost opposite direction. If the *curved* forceps were used, the ends of the blades would impinge against the pubic arch while the handles were being depressed in following the movement of backward extension. Again, owing to the depth of the posterior pelvic wall being three times as great as that of the anterior one, there is so much more difficulty in getting the occipital end of the occipitomental diameter to escape over the edge of the perineum, hence greater danger of laceration, and necessity for extra care that the occipital pole *really* shall have cleared the perineum before extension is attempted."—(King's *Obstetrics.*)

8. *Puerperal eclampsia* is an acute morbid condition occurring during pregnancy, labor, or the puerperal state, and is characterized by tonic and clonic convulsions, which affect first the voluntary and then the involuntary muscles; there is total loss of consciousness, which tends either to coma or to sleep, and the condition may terminate in recovery or death.

Hydramnios is the condition in which there is an excess of liquor amnii.

Spurious pregnancy is the condition in which a woman who is not pregnant really believes that she is pregnant, and simulates as many of the subjective symptoms of pregnancy as she is acquainted with. Often the abdominal tumor only subsides when an anesthetic is administered.

Decidua vera is the thickened mucous membrane lining the pregnant uterus.

9. The *diagonal conjugate* is the length of a line extending from the middle of the promontory of the

sacrum to the lower border of the symphysis pubis. The *true conjugate* may be determined by subtracting ½ to ¾ of an inch from the diagonal conjugate.

10. *Harris' method of dilating the cervix:* "It should never be attempted unless the cervical canal is obliterated. The woman is placed in the lithotomy position, under an anesthetic. The usual aseptic preparation is carried out. The operator then lubricates his gloved hand well with aseptic glycerin. Coning the fingers, the hand is introduced into the vagina. One finger is passed through the cervix. After a time the cervix relaxes till a second finger can be passed, then one finger after another until the whole hand is introduced. The fist is then slowly and cautiously closed in the grasp of the cervix. By this time the dilatation is sufficient for the passage of the head, and, at the same time, active uterine contractions have been established. The dilatation must be done with the least possible muscular effort, to prevent cramping of the hand. To prevent laceration of the cervix, extreme care must be used, taking plenty of time for each step. The danger of tearing is greatest in the latter part of the dilatation. The uterus is steadied by counter-pressure over the fundus, lest by pushing the uterus upward the vagina be exposed to too great strain."—(Polak's *Manual of Obstetrics.*)

(*To be concludcd*)

Miscellany.

The Treatment of Neuritis with Special Reference to Sciatica.—Harrington Sainsbury gives the treatment outlined to him by Hugh Wingfield. Sciatica is such an obstinate affection and so resistant to treatment that it has come to be regarded as an *opprobrium medicinæ.* This method of treatment is offered on account of its simplicity and effectiveness, with an additional reason of the considerable prevalence of neuralgias and myalgias among the invalided British soldiers.

The treatment consists in the direct application of the strong hydrochloric acid of the B. P., in common parlance fuming hydrochloric acid, to the skin along the line of the inflamed and painful nerve. The acid contains 31.75 per cent. of gaseous hydrochloric acid and has a specific gravity of 1.160; it is considered in the textbooks to be an *escharotic.*

The *modus operandi* is first to mark out the line of the nerve pain and tenderness as it happens to present itself in the individual. Gowers gives the following areas as the most intense pain points: (1) Above the hip joint, near the posterior iliac spine; (2) at the sciatic notch, (3) about the middle of the thigh; (4) behind the knee; (5) below the head of the fibula; (6) behind the external malleolus; (7) on the back of the foot. These areas are to be selected when present. In general it has been Sainsbury's practice to carry a broad line of application, some 1½ inches across, straight down the back of the thigh from the gluteal fold to the popliteal space; another application of like breadth for about 3 inches behind the head of the fibula along the oblique course of the external popliteal nerve at this spot; lastly, for some 5 to 6 inches behind the external malleolus directly downwards; and below the malleolus obliquely on to the dorsum of the foot.

The extent of the tenderness will serve more or less as a guide as to the extent of the application. A wad of cotton-wool, firmly compressed into a knob of the size of the knuckle of the middle finger, is used to suck up the acid, of which from one-half to a drachm will be required. The charged wad, grasped by the finger and thumb (previously vaselined), is then carried gently along the line of application above described. The degree of firmness may be increased subsequently if necessary, and the part may be painted two or three times at one sitting if the skin bears the acid well; the first application should be light and single in order to gauge the sensitiveness of the part, and if the integument happens to be thin and delicate it should receive correspondingly light treatment: Dr. Wingfield prefers to apply the acid with a camel-hair brush.

A considerable smarting is sometimes complained of; in other cases little more than a tingling or sense of mild heat is felt. After the application a light covering may be thrown over the part till the skin is dry. The smarting soon passes off and the slight redness induced disappears also; no dressing is required. Rarely, in delicate skins, is a papular rash excited; it should be allowed to subside before reapplication of the acid. Blistering has not been observed either by Dr. Wingfield or the writer. The treatment may be repeated twice a week if need be, perhaps oftener; it should be continued so long as the pain and tenderness continue. Massage may with advantage supplement the treatment, and particularly if there has been obvious wasting.

In three cases of sciatica recently admitted into the Bermondsey Military Hospital, Ladywell, the results have been striking and greatly appreciated by the patients themselves. Two of these were bad cases of long duration, and in one there was marked wasting of the muscles of the leg and thigh.—*British Medical Journal.*

Mortality in Uruguay.—The death rate of Uruguay according to the most recent compilations is 13.66 per 1000 inhabitants. In Spain during the same period it was not far in some years from double that figure. The only diseases to destroy over one person per 1000 inhabitants were pulmonary consumption and bowel troubles—the latter chiefly in the first two years of life. Of this total material, however, almost one-half the deaths could not be definitely explained, for 1.83 deaths per 1000 are set down to miscellaneous causes, while in 3.53 per 1000 no diagnosis was made. These two classifications are the bane of statistics, particularly in certain countries.

If now we take the Spanish statistics as a control, less than 1 death per 1000 is set down to undiagnosticated disease, although over 4 per cent. belong under "miscellaneous." In order to explain the increased death rate of Spain as compared with that of Uruguay the following figures may be of significance. Apparently there are in Spain 3 deaths from cerebral hemorrhage and softening of the brain to 1 in Uruguay and a similar ratio is seen in heart disease. The low incidence in Uruguay of such plagues as cancer and pneumonia is startling. Unless one brings his disease with him this republic would seem to be ideal for avoiding the very afflictions which are most deadly in the .Northern Hemisphere, always excepting tuberculosis. The foregoing data are to be found in the Bulletin of the Office International d'Hygiène Publique for July.

THE ARMY MEDICAL MUSEUMS.

BY R. W. SHUFELDT, M.D.,

WASHINGTON, D. C.

MAJOR, MEDICAL CORPS, U. S. A. (RETIRED.)

To all those interested in the literature of medicine and surgery, it is well known that, early in our Civil War, steps were promptly inaugurated not only to collect together all possible material sent in from the operating tents on the fields of battle and from the great army of hospitals which had come into existence, but also to gather from various other sources anything and everything which would in any way illustrate those two most important departments of the healing art, in so far as they referred to military practice. The then Surgeon General of the Army, and various other far-seeing officers of the medical department of that branch of the government, were the ones principally responsible for the prompt action that was taken in this matter. Through these several channels it was arranged that all the material thus preserved should come to Washington, and there be properly taken care of until such time as it could be duly assorted, placed on exhibition, and otherwise made available for the use of the physicians and surgeons of the world.

In the main this material consisted of medical and surgical specimens collected at post mortems made upon officers and men of our armies in the field; of

FIG. 1.—The present Army Medical Museum in Washington.

parts removed at operations upon the same; of missiles and weapons of offense and defense; of contrivances for the transportation and care of the wounded—indeed, of anything and everything that would in any way illustrate military medicine and surgery along the lines indicated. At first this valuable material was duly stored in any building in Washington that could be obtained to accommodate it; but so rapid was its accumulation, and so formidable was it in amount, that after various housings it

FIG. 2.—Main museum hall in the present building.

finally came to be placed on exhibition in the old Ford's Theater on Tenth Street in that city, where it remained for many years, and long after the war was over.

During all this time there also came to this Army Medical Museum—as it was eventually called—all the field reports of the army surgeons at the front, and likewise the special histories of specimens and other material forwarded. At different periods in the history of all this, various medical officers of rank were appointed by the Surgeon General to take charge of this museum; and in due time a large body of workers, having divers duties to perform in connection with what this great collection in a few years came to be, were also made a part of the force required to care for it and to put it in shape for practical use. In a way, too, it was connected with the Pension Bureau, the whole forming its due part of the Surgeon General's Office of the Army

Later on, classification of cases came into play; a taxonomy of material; a weeding out of the non-essential cases and histories, and a placing in order for publication with hundreds of illustrations of all the rest. This required a long time and many

FIG. 3.—Cases on lower floor of the present Museum, showing crowded condition of the specimens.

hands and minds to accomplish; but the final outcome of it all was a superb series of quarto volumes and other treatises, which constitute the most formidable, as well as the most useful contribution, as a whole, to military medicine and surgery that the world has ever known.

As years passed, the old Ford's Theater building —known far and wide as the Army Medical Museum—came to be altogether too small to contain this growing collection, and it was abundantly added to from many sources long after the Civil War had ended. Then, too, it was not fireproof, making it especially dangerous on account of the great quantities of alcohol in the building, used to preserve the specimens; and its floorings were too insecure to sustain the great weight demanded of them by reason of the large number of persons and material occupying each of them. This dangerous state of things was constantly called to the attention of Congress, with the view of securing a new building, one in all particulars adequate to accommodate this priceless collection. Finally, one day a crash came —a floor collapsed; several clerks were either killed or wounded, and not long after the government supplied the money for a new building, to which in due time the entire collection, the superb medical and surgical library, and the rest were removed.

The history of all this, and the happenings of all the years that have followed, has only very recently (September, 1917) been compiled and properly illustrated by one of the veterans of the museum, Dr. D. S. Lamb, a member of the present, as well as the old staff of the institution. This very important and most interesting compilation is entirely ready for publication; when issued it will form one of the series of Bulletins published by the Surgeon General's Office of the Army. It is temporarily held in check owing to the lack of funds to issue it—a barrier that should not be allowed to block the way for the prompt publication of such literature for a single day. This, however, is a point that will be touched upon in another connection in the near future.

As stated, Dr. Lamb is still a member of the museum's staff, while other departments are under the charge of regular officers of the Army Medical Corps, Col. William O. Owen having the museum, and Col. Champe C. McCulloch, Jr., the magnificent library that the building harbors. The latter department is in a flourishing condition, and many new books, pamphlets, journals, and all current medical literature are daily added to its shelves.

This, however, is not the case with the museum.

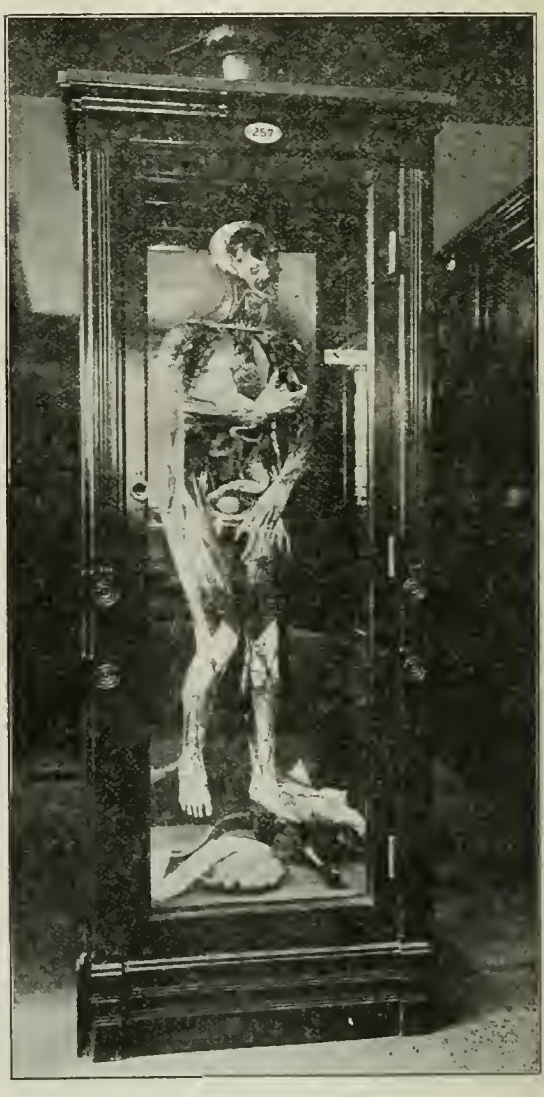

FIG. 4.—Human manikin on lower floor of the present Museum.

For many years past every nook and corner in that division have been filled to the utmost capacity by the various objects constituting the collection as a whole. From the standpoints of antiquity and history, this collection will always be of enormous

value; but from the viewpoint of a growing collection, and an up-to-date exposition of modern medicine in all of its varied departments, it has, for only too long a time, been a supreme joke. Strenuous attempts from many, often influential sources have been made for years to remedy this crying need for a new building. Beautiful plans for the structure have been prepared by the well-known Washington architect, Mr. A. Burch FitzSimons, while a fine location for a new building has likewise been selected and approved. Here, however, the matter at present rests; the financial means are not yet in sight to erect and properly equip the building. Colonel Owen is doing everything in his power to further these much needed new acommodations, but with little or no avail up to date. Unfortunately he cannot give it his entire attention; in these strenuous war times many other matters of importance seriously cut into his available time. There is large room vacant for another officer of the medical department of the proper rank, to second his efforts in this matter and field of operations.

nishing the material that results from operations of many, many kinds. The enemy's weapons, of every conceivable description, will soon be captured by our troops at the front; new methods for transporting the wounded are already in operation—indeed, all this, with much else besides of the greatest possible value to our physicians and surgeons of the future, in civil as well as in military life, needs to be cared for immediately, and proper accommodations of a permanent character made for it in Washington. As many reports as possible of medical officers at the various seats of war should be accompanied by the removed parts at operations, when of especial interest. There should be a photographic department at the museum to illustrate all this history, and, whenever possible, photographs of operations and conditions in the field of a medical character should also be sent in with the reports of medical officers. In fact, the necessary steps to furnish a complete medical and surgical history of the present war, in all the various branches and departments involved—in so far as this country is

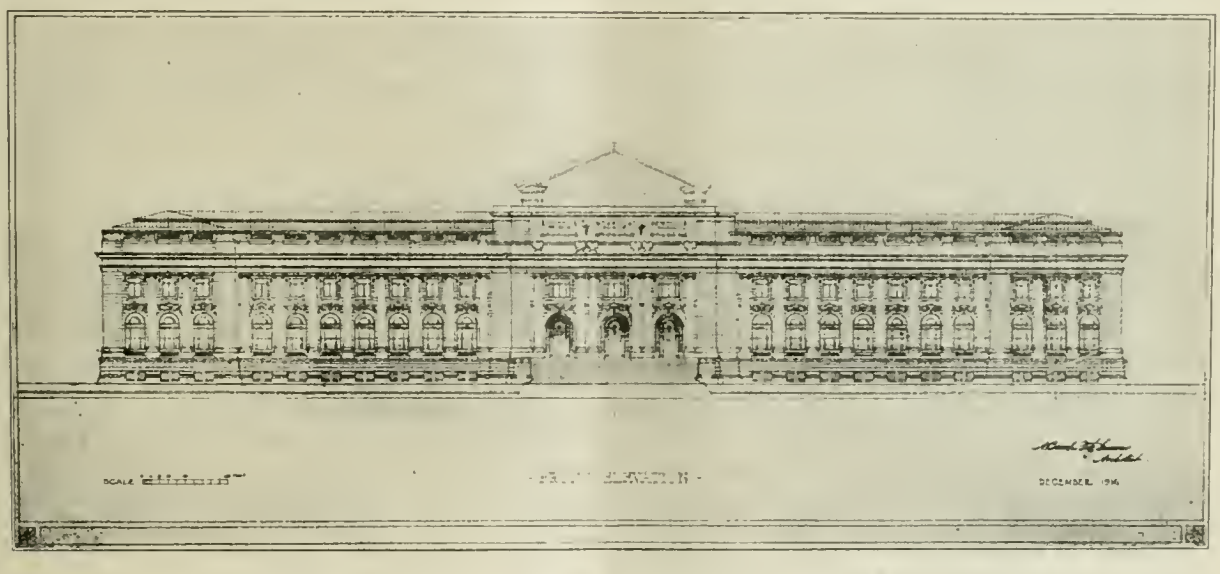

Fig. 5.—Front elevation of the proposed new building of the Army Medical Museum.

The above referred to "The Medical and Surgical History of the Civil War" is already past history, as many, many years have gone by since it was published. It is reflected in the museum collection of specimens, illustrating the then military medical and surgical practice. This is likewise true of the machinery, missiles, weapons, contrivances for bodily defense, and similar exhibits in the collection. All these, in each and all of the departments, have, in due course, entirely changed. Different methods of treatment of every conceivable character have been instituted; the nature of many wounds, burns, and injuries of all kinds is different, owing to the modern arms, tools, gases, and the like that inflict them. All this needs most complete illustration in kind; it needs a *new museum* of great capacity to contain the required collection, and the proper assistance to conduct it.

In so far as the United States is concerned, the war is still in its earliest stages; but very soon things will be different. The field hospitals, operating tables, dead and wounded on the fields of battle, general hospitals here and abroad, will soon be furconcerned—should be substantially put on foot without another day's delay.

All this will require the necessary appropriations to be made promptly by Congress—that is, the means to erect the new museum building; to equip it properly, and to bring into existence, under Colonel Owen's command, the necessary additions to the staff and other force to care for that history, until it is safely published and landed as a series of sumptuous quarto volumes on the shelves of the *new* library in the *new* Army Medical Museum; and this latter erected as designed, on the site selected at the capital of these United States of America.

3356 Eighteenth Street.

Suprarenal Asystole. — The secretion of the suprarenals is indispensable for cardiac contractions in the opinion of Josué. An hypertrophy of the heart means a parallel hypertrophy of the suprarenals. The weight of the heart should be thirty fold that of the latter. If there is absence of this compensatory enlargement, suprarenal asystole may develop with sudden death.—*Paris Médical.*

ALCOHOL AND THERAPEUTICS.

By EDWARD HUNTINGTON WILLIAMS, M.D.,

LOS ANGELES, CAL.

SOMETHING like five years ago, at a meeting of the World's W. C. T. U., a somewhat overwrought feminine member of the audience suggested that a federal law should be passed forbidding doctors to use alcohol in any form in the practice of their profession. The suggestion was quietly but firmly suppressed by the more thoughtful and less choleric members of the conference, because they believed that, although alcohol was a bad master, it was a good servant—a good medical servant, at least.

Very few members of the medical profession, of course, ever heard of this little flash-pan incident; and those who did for the most part regarded it as one of those pleasantries which characterize our emotional, over-petticoated present day legislation. When, however, the House of Delegates of our great American Medical Association at the 1917 meeting tacitly championed the suppressed W. C. T. U. member's suggestion by declaring that alcohol's "use in therapeutics, as a tonic or a stimulant or as a food has no scientific basis," and that its use as a therapeutic agent should be discouraged, it was evident that our temperance fanatic's little pleasantry had been making progress. To some, at least, it seemed to have developed into a formidable medical boomerang.

It has been suggested that this action of the House of Delegates may have been merely a "war measure" —an attempt to emphasize the evils of alcoholic abuses at this critical time, and largely for lay consumption. Certainly, it was contrary to the teaching of practically every medical text-book, and not in accord with the experiences of most physicians.

But, unfortunately, the laymen of America have a habit of thinking for themselves, even in medical matters. We have taught them to do so. And, in any event, it is futile to try to convince a man who has lulled a toothache, eased a "colic," or warmed a benumbed body with some form of spirits, that he he had done nothing of the kind. We are likely to lose his confidence if we attempt to do so. And, it is not merely his confidence in us individually that may be affected, but confidence in the whole fabric of modern medicine.

Moreover, it is evident to any one if practically all medical books teach that alcohol is a useful drug; and that meanwhile the official sponsors for the greatest medical organization of the country declare that it is not—it is quite evident that one or the other must be mistaken. And this will lead inevitably to the suspicion that if they are mistaken about the effects of such a universal drug as alcohol, which has been studied since ancient times, they are much more likely to be mistaken about the less well known drugs, such as digitalis, opium, belladonna, and a dozen others.

Kraepelin, the champion of temperance, has pointed out that observations about therapeutics, to be of value, must "harmonize with the experiences of every-day life." The dogmatic statements of the House of Delegates, therefore, may be measured by this standard, and, if correct, should harmonize with the opinions of the majority of physiologists, pharmacologists, and clinicians. As a matter of fact they do not "harmonize" at all, as any physician may demonstrate for himself by reaching into his bookcase and picking at random almost any one of his text-books. The result will be the same whether the volume he hits upon happens to be one of the old sheep-bound books, or one of the more recent cloth creations.

As I write this, a copy of the MEDICAL RECORD for August 18, 1917, comes to my desk. On the first page I find an article by Dr. Horatio C. Wood, Jr., in which he says: "Personally, I am convinced that, under certain circumstances, alcohol is a valuable remedy." Dr. Hobart Amory Hare went on record two months earlier, in the *Journal of the A. M. A.*, protesting against the action of the House of Delegates in condemning the medicinal use of alcohol as being, "in the opinion of many eminent medical men, untrue and not supported by the majority of evidence." And it is probable that the opinions expressed by Dr. Wood and Dr. Hare indicate the belief of a vast majority of physicians everywhere. Moreover, most experimental research workers have found evidence that supports the views of the clinicians.

Thus, Sir Michael Foster, acting as spokesman for the International Physiological Congress, asserted that: " . . . The results of careful experiments show that alcohol, so taken (in diluted form and in small doses), is oxidized within the body and so supplies energy like common articles of food, and that it is physiologically incorrect to designate it as a poison, that is, a substance which can only do harm and never do good to the body." Sir Michael's opinion was expressed several years ago; but a majority of "up to date" physiologists still accept the opinion of the great Englishman. Howell of Johns Hopkins, for example, asserts in his text-book of physiology as the result of experiments, that "These results indicate, therefore, that alcohol may actually take the place physiologically of fat or carbohydrates as a source of energy and as a protector of protein metabolism." And this view is held by Newman, Atwater, and most other competent observers.

These physiologists, to be sure, are referring to the action of alcohol in normal, rather than pathological conditions. But clinicians who have earned the right to a hearing, not only advocate the use of alcohol as a therapeutic agent, but are ready to name specific conditions in which it is helpful. Osler, for example, says: "I should be sorry to give up its use in the severe forms of enteric and pneumonia." And Dr. G. B. Twitchell, writing in the *Boston Medical and Surgical Journal*, asserts that when alcohol is given in the severe cases of pneumonia where the patient appears moribund—a condition that every practitioner has seen, and dreads—the temperature comes down a little, the pulse is quieted and strengthened, and the livid face is flushed. "Keep it up and the case, apparently lost, will meet the crisis successfully. The trouble from alcohol in this disease is that we give it too sparingly."

These are typical examples of the kind of observations one finds everywhere in authoritative medical literature. They dispute flatly the assertion of the House of Delegates that alcohol does not act as a stimulant in the ordinarily accepted meaning of the

term. "That it does act as a powerful cordial in heart failure," says Sir Clifford Allbutt, "is undeniable by any one who has averted a faint by a glass of wine, or watched its effect upon certain feeble, irregular pulses."

It is not merely as a "stimulant," however, that alcohol has made a place for itself in therapeutics. Indeed, judged by medical literature, it is doubtful if any other single drug has been so highly and universally recommended for the treatment of so many specific conditions, even in recent years, as alcohol.

Thus we find such men as Dr. Abraham Jacobi, former president of the American Medical Association, accurate observer, and a man of tremendous experience, advocating the use of heroic doses of whisky in the treatment of sepsis, and emphasizing what he believes to be a fact that "no amount of whisky will produce intoxication when its effects are wanted to combat sepsis." And Dr. George H. Weaver declaring that: "For general toxic disturbances, manifested by rapid and irregular heart, occasionally by slow heart, and sometimes by vomiting, alcohol is to be given freely and frequently repeated. Strychnine is of value, but not equally with alcohol."

Evidently, Dr. Weaver takes issue with those who maintain that alcohol may be dispensed with in the practice of medicine because other less harmful substances act equally well.

In another field, Lathem, writing on the treatment of tuberculosis in the London *Practitioner*, says: "Experience has shown that alcohol is of the greatest possible service when fever is present. It saves the body protein, stimulates the appetite, and in small doses hastens gastric digestion." And the American physicians, Butler, Favill, and Norman Bridge, in the volume for which they stand sponsors, agree that "the use of alcohol to relieve gastric distress is rational and effective."

Speaking of the treatment of diabetes, Meyer and Gottlieb assert that: "In diabetic acidosis the administration of alcohol like that of carbohydrates decreases the formation of acetone, and also that of the pathologically more important oxybutyric acid." And von Noorden declares that, in certain phases of diabetes, whisky in heroic does—a "veritable drenching of the system"—is life saving. At these critical periods he gives no food whatever. Yet "large quantities of whisky are well borne even when the patient is not accustomed to them. It is followed by a large reduction of ketonuria and the general condition of the patient is greatly improved."

In acute infectious diseases, to name but one instance, Dr. Jay F. Schamberg says that in the treatment of variola: "It is a wise plan not to wait for the development of such manifestations (tremor, pallor, delirium, etc.), but to anticipate them and strengthen the vital forces by the timely employment of alcohol." And similar statements as regards the effects of alcohol are found everywhere in medical literature.

Thus it appears that in the printed opinions of a vast majority of authoritative writers, alcohol ranges in therapeutic usefulness in the treatment of certain conditions, between a substance that is positively helpful to one that is absolutely indispensable. And the conditions for which it has been found helpful include many varied types of maladies, from acute infections to chronic organic diseases.

Yet we are asked to believe that these assertions are all wrong—that our observers did not see what they thought they did at all. In short, the action of the House of Delegates leaves us no middle ground; we are obliged to doubt the wisdom of a vast majority of observers who believe that alcohol is a useful remedy, or doubt the wisdom of the House of Delegates in declaring that it is not.

This rift in medical harmony would be of little importance if almost any remedy other than alcohol were involved. But, unfortunately, the problem of alcohol is not merely a medical one, but a political, moral, ethical, financial, and religious one as well. Needless to say, therefore, the action of the House of Delegates has stirred up a tempest, whereas, in a less emotional field it would scarcely have caused a ripple.

Roughly speaking, the people who are being directly affected by the action of the House of Delegates fall into one of four groups, namely, physicians, laymen in general, temperance advocates (including both the sincere and the professional types), and the opponents to scientific medicine, most of whom belong to one or another of the "drugless healing" cults.

Curiously enough, the persons whose opinions seem to be least influenced by the action of their official representatives, are the members of the first group, the physicians. The reason for this is readily understood. Every physician, even of very limited clinical experience, has had occasion to test the therapeutic effects of alcohol. Mostly he has been able to note what he considers some very definite effects in certain cases. It is what he expects, because the weight of clinical evidence has taught him to expect it. And once this physician has tided a pneumonia case over a critical period with alcohol, or "watched its effect upon certain feeble, irregular pulses," as inevitably he will, he is not likely to change his opinion about what he considers the "evidence of his own senses." In any event, he is accustomed to "going it alone" in the treatment of his cases; and it will cause him very little perturbation to know that certain officials of his Society do not see things as he does.

As far as the layman is concerned, the decision of the House of Delegates is likely to have about as little effect as in the case of the average physician. The layman has had the subject of strong drink hammered into him from so many different angles, and for so long, that for the most part his ideas about it have become ingrained. In any event, if he has any doubt in the matter he will probably ask his family physician about it the next time he sees him, and will be at once set right in the matter.

But the effect produced in the ranks of two other groups of people—the professional prohibitionist and the drugless healing votaries, professional and otherwise—is very, very different. Even before the ink was dry on the announcements of the action of the House of Delegates, the one class was "sharpening her claws and the other fingering its axe helve." Thus Dr. Hare, who did not agree with the opinion of the Council that alcohol was useless in medicine, received a letter from a body interested in "prohibition" even before he could finish his

letter stating his opinion, asking him to "telegraph the President" confirming the statement of the Council. This represents a characteristic attitude of mind of such people, but it is probably merely of "pin prick" significance. For "temperance cranks" are so accustomed to juggling alleged facts which have no particular relationship to truth, that one additional item is of little consequence.

The really important effect—the thing that will keep cropping out continually, and making its appearance from every legislative angle—is the fact that the "drugless healers" and their followers have been handed an official "jimmy," fashioned very much to their liking. It is now a matter of official record that the whole medical fraternity has been entirely mistaken about the use of one of its most important drugs. Which is precisely what the drugless healers have contended all the time about *all* drugs.

And make no mistake, this army of drugless healers is far from being a contemptible one. Its variously ramifying branches, it is estimated, take in one quarter of the population of this country—twenty-five million scalp-hunters of regular practitioners—who have won pretty decisive victories in practically every State in the Union already, and are pressing the fight everywhere. One need not exercise any very great amount of imagination to conceive the use these fighters will make (are making, indeed, at this very moment) of the discord in the ranks of the medical men—the diametrically opposed views about the effects of the oldest and most thoroughly studied drug in the whole category.

It is this disagreement about the effects of alcohol as a therapeutic agent, rather than the actual fact about it, that is unfortunate. If it were a clearly established fact that we had been mistaken about any phase of medicine, the sooner the error was recognized officially the better, regardless of temporary consequences. But in this case the facts are subordinated by the weight of mere official opinions, with the preponderance of evidence indicating that alcohol is indeed a very useful therapeutic agent.

Moreover, there seems to have been a doubt even in the minds of the members of the Council of Health and Public Instruction that declared the use of alcohol in therapeutics "has no scientific basis," if we may take the word of its secretary, Frederick R. Green, in a statement printed in the *Journal of the A. M. A.* for July 21, 1917. "The subject was not taken up by the Council on its own initiative," says Dr. Green. "At the Detroit session a memorial from the National W. C. T. U. was presented to the Association through the secretary in which the Association was asked for an expression of opinion on alcohol from a social rather than a therapeutic standpoint."

This led to the action taken later by the Council and approved by the House of Delegates. But, despite the fact that the House of Delegates have gone on record in declaring the use of alcohol to be "unscientific," it appears, according to Dr. Green, that the Council attributed a certain flexibility to the word "scientific" which is sarcely permissible in the field of exact science.

"The resolutions adopted by the House of Delegates," writes Dr. Green, "are an expression of opinion on the part of this representative body of the medical profession of the United States as to the harmfulness of alcohol, *especially from a social standpoint.* They are to be regarded as a statement of general principles rather than a dogmatic, dictatorial, and infallible rule to be applied to all cases without exception." And he adds: "They will doubtless be so considered by the mapority of the members of the Association."

It appears, then, that the effects of alcohol were considered "from a social standpoint" rather than a strictly scientific one by the members of the Council. But, unfortunately, they failed to make this important point entirely clear in their official statement.

NASAL INSUFFLATIONS IN THE DIAGNOSIS, PROGNOSIS, AND TREATMENT OF TUBERCULOSIS.

By OWEN PAGET, M.D.,

FREEMANTLE, WEST AUSTRALIA.

MEDICAL OFFICER OF HEALTH OF FREEMANTLE.

In the Medical Record of February 16, 1915, is published a paper of mine entitled "The Prevention, the Treatment, and the Cure of Tuberculosis." The theoretical considerations put forward in that paper were further elaborated in two later papers. The first of these, "Epithelial Function in Relation to Disease," was published in the Medical Record on Sept. 18, 1915, and the second, "Autosecretion in the Treatment of Cancer," was printed in the same periodical on April 22, 1916.

These articles contain the results of theoretical considerations and experimental work. Even to those interested in them, they must seem lacking in practicality, and for this reason I am publishing the following cases to show the everyday application of these ideas in the diagnosis, prognosis, and treatment of tuberculosis.

Although engaged a large part of the time since the commencement of the war in military duties, I have yet found opportunity to carry out investigations on some 200 cases of tuberculosis. A large majority of these cases were hopeless derelicts. My technique was constantly found to be faulty and lacked what must be the essentials of any form of satisfactory treatment, namely, (1) simplicity of application by others; (2) uniformity of action in all cases; (3) obviously beneficial results; (4) absence of harmful effects. It is not of great interest to recite my mistakes, my difficulties, or hostile criticisms. At times these have been such as almost to dishearten me. It is, however, important to state definitely the premises on which my methods of treatment are based, for much criticism engages matters of side issue, and is irrelevant.

My hypothesis is as follows:

1. Epithelial cells are probably a primary and essential factor of our resistance against disease.

2. They so act by internally secreting, when stimulated to do so, what may be called for want of a better term, "antibodies."

3. The epithelial cells of the turbinates and nasal sinuses seem to have a special capacity to form "antibodies" against tuberculosis.

4. If this is the case, one would expect to find that the application as a fine powder of dead tubercle bacilli to the nasal mucous membrane would lead to some modification of tuberculosis, even when established in such organs as the lungs, bones, and glands.

5. Experimentally I have conclusively convinced myself that this is the case, and physicians who have seen some of my cases consider me justified in my beliefs.

6. Through the courtesy and assistance of Messrs. Parke Davis & Co. I have been able to carry out a considerable number of experiments with tablet preparations of dead tubercle bacilli insufflated on to the nasal mucous membrane.

7. I have, however, given up these preparations for certain mechanical and technical reasons, of which perhaps bulk of powder, variation in virulence, and necessity for constant administration were among the most important.

8. I now employ, as in my original experiments, Tuberculin BE, but my present method of application is a vast improvement on that formerly.

9. My reasons for employing Tuberclin BE are the same as those guiding physicians who employ strychnine rather than nux vomica, and quinine rather than cinchona bark. It is neater, can be used in a very small bulk, is more potent, and less variable in its action.

10. But I must enter a most sincere protest against suggestions that this is a treatment by tuberculin. It is a treatment by broken-up tubercle bacilli applied to the mucous membrane of the nose. I know full well the results of tuberculin injected into the system. These haphazard effects and the misfortunes arising from the use of tuberculin hypodermically can, I think, be explained by my theories, but it will take too long to discuss such side issues. I will merely reiterate that in employing Tuberculin BE, I am simply using an emulsion of tubercle bacilli, which, on account of its smallness of bulk, disintegration, and uniformity of strength, is peculiarly useful for my method of treatment. The universal appreciation by physicians of standardized drugs is an analogous sentiment to my own. Both express a desire for accuracy of dosage and reaction. In bringing to the notice of the medical profession the cases to be narrated, I am guided by certain definite reasons: Perhaps the first of these is to draw the attention of physicians to my theories, in which I have such profound belief. Again, I have now carried out so many experiments with their varied results of failures, brilliant success, and partial success, that I am anxious to detail my methods, which I believe now will give uniformity of result. And lastly it is extremely probable that I shall shortly be reengaged in military work, with possibly no chances of carrying on my investigations and treatment of tuberculosis. The publishing of these cases is regarded as only a stepping stone to a series of 50 consecutive cases, watched over a period of, say, 6 months.

But first I will explain the technique of application, for much of the simplicity of which I am indebted to Dr. T. P. Woo, late assistant Resident Medical Officer at the Brompton Hospital, London.

The instrument consists of (1) a glass tube bent at a right angle. One end of the tube, the end, in fact, which is passed into the nose, is drawn out to a fairly fine point. The other end is slightly flanged outward to facilitate emptying the powder into the tube. (2) An ordinary rubber bulb syringe with a nozzle, which will fit into the large end of the glass tube.

The method of procedure is as follows: The dose of tuberculin BE powder, which varies from mgm. 1 20 in severe cases to mgm. 1 10 in the more ordinary cases, is poured into the glass tube at the large opening. The outward turned flange has the good quality of preventing the powder from falling outside the tube. It is essential that the tube be perfectly dry inside, otherwise the powder sticks and cannot be insufflated. The powder when poured into the tube naturally stops at the angle. The tube is next taken in the hand, and with care to prevent the powder falling out, the pointed end is directed into the nose. This end should be carried as high up into the nostril as can be comfortably tolerated by the patient, and a matter of great importance is that the point shall be directed toward the frontal sinus. On no account should the tube be directed backward toward the pharynx. After the tube is in place the patient is directed to hold it firmly in his hand. He must hold it firmly, as otherwise there is a danger at the moment of insufflation

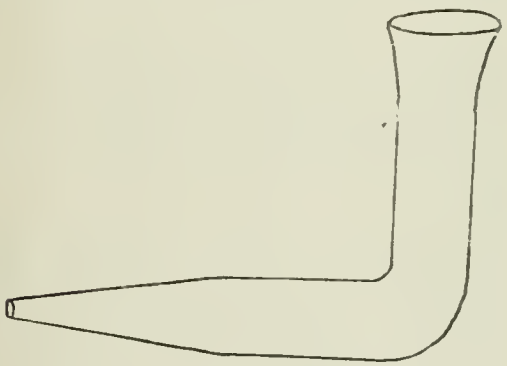

Fig. 1.—Tube for nasal application.

of the point of the tube moving, and perhaps causing pain and discomfort in the patient's nose. The glass tube in place, and firmly held by the patient, the physician inserts the nozzle of the rubber-bulb syringe into the large end of the glass tube and by a quick squeeze blows the powder in the tube high up into the nose.

Patients can generally tell by a transient tingling the point where the powder has reached, and when they indicate the region of the frontal sinuses or over the eyebrows I am in the habit of regarding the insufflation as a successful one.

It seems as if the capacity of the epithelial cells to form antibodies is more highly developed in the upper regions of the nose than in the region of the lower part of the septum, and the inferior turbinates. Pouring the powder into the tube, inserting the tube into the nostril, and squeezing the insufflator, takes perhaps one minute.

The advantage of this method in hospitals is quite marked. It is cheap. Each patient has his own glass tube, and all the medical officer requires is a rubber-bulb syringe, with which he can insufflate numberless patients.

I have now been investigating the relationship be-

tween tuberculosis and the nasal mucous membrane for over four years, and though through faulty technique and many other blunders I have had failures, yet on the other hand, whether using semi-dried sputum, or sputum prepared by ether and alcohol, or dead tubercle bacilli insufflation, or tuberculin BE insufflations, I have obtained results which other medical men, who either attended on or saw the cases, considered might justly be ascribed to the treatment.

Of course, there are differences in the reactions and methods of administration of these different products, but certain phenomena remain constant. For instance, in a severe case of tuberculosis, the period of six weeks constantly recurs as the period of time which it takes definitely to abate the disease.

So far as the temperature is concerned, this can be brought down by crisis or lysis. Crisis entails what may be called shock doses, with a preliminary rise of temperature of two or three degrees, and even more. The phenomena arising under these circumstances are similar to those occurring in the crisis of pneumococcic pneumonia; and I am convinced that the process which I bring about is akin to that which causes an ordinary pneumonia to resolve. And this resolution of an ordinary pneumonia is an occurrence which we accept, though we do not explain. Another point is that all the symptoms improve concurrently, and to me one of the most striking indications of the probability of success is the change in the appearance of the skin. I am unable to describe this change more graphically than to say that it looks less muddy and more healthy.

A criticism which may be made is that the treatment causes a temporary rise of temperature, which must be harmful. I accept the fact that tuberculin injected hypodermically in too large doses produces sometimes very harmful effects, and can actually cause extension of disease. But though I have given large doses of tuberculin as insufflations, and produced severe reactions of temperature, I have not been able to find that they produced extension of disease, and some of these cases have been carefully examined by medical men skilled in tuberculosis work. These severely reacting cases have, after the reaction passed off, done remarkably well. Again, the rise in temperature may be due to two causes: (1) A local reaction in the nose akin to a severe cold; (2) the general reaction.

Now, though I do not advocate a violent reaction, on the other hand the meaning of the temperature does not seem to be always grasped by the tuberculosis physician. To me, though a raised temperature expresses an insufficient capacity to resist disease, yet on the other hand it expresses an endeavor to do so up to the height of such capacity; and if we artificially increase resistance by the production of antibodies then such endeavors may be successful.

The tuberculosis physician feels most secure when both he and his patient are doing nothing. Yet he is often illogical, for does he not prescribe at times autoinoculation treatment by forced exercise, which raises the temperature? Perhaps it is as well to discuss here the character of the temperature curve produced by insufflations, as also its relation to the malady and its effect on the patient. The height and the length of the rise of the temperature produced by insufflations vary, and are, I believe, governed by the size of the dose and the already existing capacity of the patient to resist the disease.

In the case of a large dosage, such as mgm. ½, a sharp rise of two or even more degrees may take place suddenly, and the patient may also react in himself; that is, look flushed and ill. The rise in temperature is followed by a fall, which is that of either crisis or lysis.

Contrary to the experience with tuberculin (hypodermically), I have only found good following these cases, but I do not advise such dosage, and consider that it may certainly be harmful in long-standing cases and in patients over 40.

The fall in temperature is accompanied by a general improvement of all the symptoms. The character of the temperature curve produced by moderate dosage is best studied by examining the accompanying chart of a former case.

When treatment commenced, the temperature level was from 99° to 101°. Treatment consisted of insufflation of mgm. 1/10 on four consecutive days. The day after the last insufflation the temperature rose to 102°, and from then onward steadily fell, so that eight days after the last insufflation it was down to the 98-100° level.

In such a manner can a 101-102° type of temperature be brought down to the 99° level in six weeks, for the dosage is repeated when a lower level is definitely reached.

With the fall in temperature there is a corresponding improvement in physical signs and general condition. Usually, even at the height of the curve, the patient's appetite is good, and he is taking his food freely and willingly.

My method of administration for such cases as cervical adenitis and other office cases is an insufflation every second day. These cases, which have an evening temperature of 98.6° to 99°, seem to react very little, and after about the tenth day settle down to normal. It is from the tenth day on that their general condition starts improving, and especially the appetite.

In tuberculosis, in a general way, the temperature is an expression of the virulence of the malady. The argument that a rise of temperature for a day or two is harmful when it is followed by a lengthy lowering of temperature and general improvement of symptoms is absurd. I regard the rise in temperature as merely an expression of the poverty of natural resistance.

My theories as to the action and reaction of epithelial cells are so entirely my own, and as yet so imperfect, that the discussion of a possible analogy to circumstances which arise when microbic products are injected hypodermically, and hence directly into the circulation, is futile.

As a matter of fact, as said before, the rise in temperature is probably produced by two causes: (1) A local reaction akin to a severe cold; and (2) a general reaction.

The desire to eliminate the local reaction is one of my reasons for adopting tuberculin rather than dead tubercle bacilli. The effect of the rise of temperature on the patient when moderate doses are used seems to be very small. As already stated,

their appetite is usually singularly good at this time, and I have not noticed any extension of physical signs.

What is the value of insufflations in simplifying the practical diagnosis of tuberculosis and in enabling us to prognose the severity of the attack?—The diagnosis of tuberculosis, even with expert tuberculosis physicians and bacteriologists in a well-ordered institution, is not always easy. To the practitioner who sees the early case it causes endless bother, especially in those cases which are expressed by a general malaise with few or very indefinite physical signs. In military work it is as bad, if not worse.

Now, my method of treatment by insufflations removes all these difficulties. The physician can, without alarming his patient, say that he will test the possibility of the disease being present. He gives an insufflation of mgm. 1/12 every second day for six doses. This occupies a period of roughly a fortnight. If at the end of that time, or before, the patient's temperature has definitely reacted, then it is probably a severe case.

On the other hand, if the patient is definitely improved in health, with a fall of temperature to normal, then a diagnosis of tuberculosis in a mild form is made, and the insufflations as a treatment are carried on for another two to four weeks. At the end of this time the patient should, in a mild and early case, be either well or sufficiently nearly so to require only a few days' holiday. A reaction with insufflations of moderate dosage is an expression of a distinctly enfeebled resistance against the disease, and the amount of reaction is probably in direct proportion to the poverty of resisting power, and hence enables a definite prognosis to be given.

If a decided reaction is produced with moderate dosage the patient should be treated on conventional tuberculosis lines, in so far as rest in bed is concerned. He should, in fact, be regarded in the same light as one suffering from enteric fever.

The severity of the attack having been estimated by the temperature and by the reaction, the treatment by insufflations should be continued until practically no reaction is produced. To what extent the nasal sinuses are always or never affected by tuberculosis it is difficult to state. I am inclining more and more to the belief in such affection. Certain it is that cases of tuberculosis have with exceeding frequency postnasal catarrh. The insufflations of tuberculin, though they temporarily produce congestion of the nasal sinuses, and may even cause bleeding, ultimately seem to have a distinctly beneficial effect upon the catarrh.

Congestion of the frontal sinuses often seems to be a precursor of a febrile attack in tuberculosis, and it seems as if an insufflation of tuberculin can not only relieve this but even abort the attack of fever.

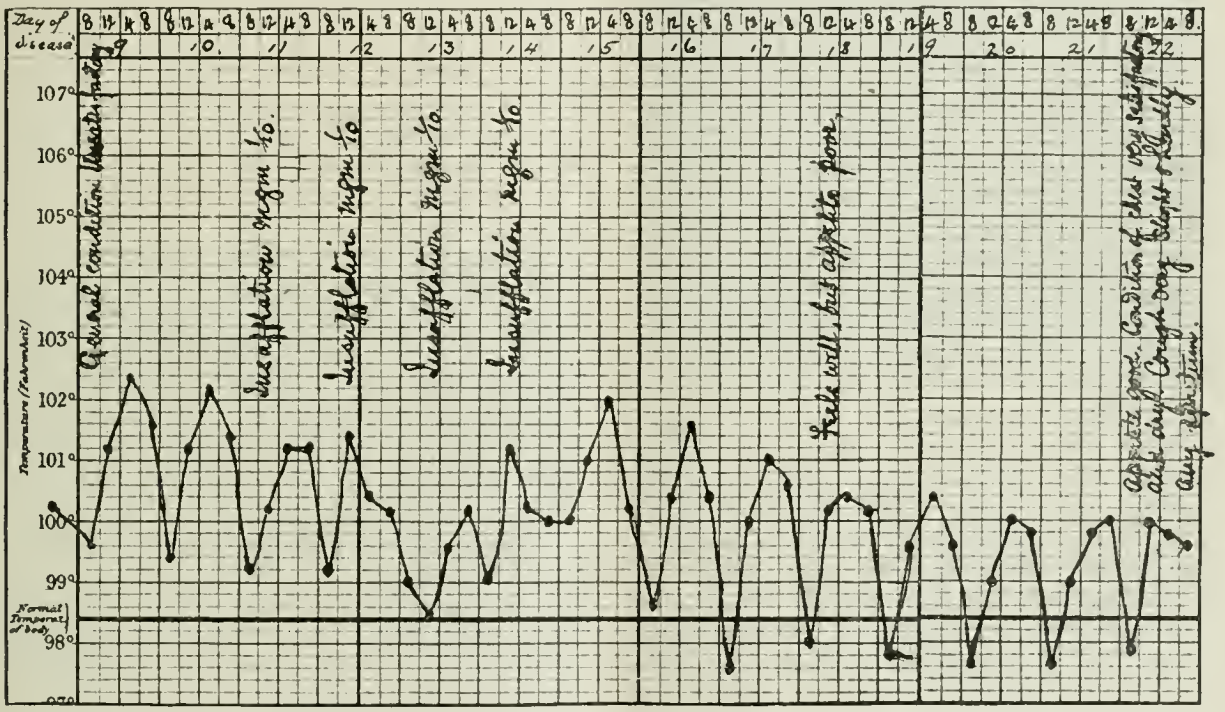

Fig. 2.—Temperature curve in a course of nasal insufflation.

To relieve the congestion in the nose I employ either a normal saline wash or a paraffin inhalant with a nasal spray. As stated in my original paper, the acquirement of a permanent immunity is accomplished by establishing nose breathing. This can be done by means of nasal props or by an operation such as the one described by me in the *Medical Review of Reviews* for 1915. I feel more justified than ever in stating this, but if a case relapse through carelessness in wearing the props a fresh immunity can easily be established by means of insufflations.

The following cases are representative of medical and surgical tuberculosis:

Case I.—S. M., age 5½. Mother had tuberculosis. Stocky built, well nourished boy, with depressed bridge to his nose. Suffers from adenoids and decayed teeth. Just below the angle of each jaw there is a large lump due to enlarged cervical glands. The swelling is larger on the left side than on the right, possibly the result of a crack of the skin at the point where the lobe of

the pinna joins the cheek. These enlarged glands are said to be of two years' duration. The treatment, which consisted of insufflations of 1/10 mgm. tuberculin BE every second day in alternate nostrils was carried on for six weeks. No nasal props were inserted. At the end of six weeks the glands had been reduced 70 per cent. and the general condition was excellent.

In this case the treatment should, of course, have been, first of all, the removal of the adenoids and the septic teeth, and afterward the insufflations. But I was anxious to ascertain whether it was possible to produce beneficial effects under adverse circumstances and to convince myself that the result was due to the insufflations and not to other treatment.

Case II.—M. S., male, age 28, lawyer; disease. cervical adenitis. Nine years ago had an attack of pneumonia, probably tuberculous. Shortly after this he was struck by a cricket ball on the neck, and after that there was extensive enlargement of the cervical glands, especially on the left side. I operated at that time and removed the whole of the glands on the left side from mastoid to clavicle. As isolated glands kept cropping up on the right side, hypodermic injections of tuberculin were given. The benefit received from these injections was not great, for in the end I had to send my patient up on to a cattle station (the equivalent of an American ranch) and advise him to live out of doors and eat as much meat as possible. He remained there one year with benefit and then returned to his professional work. Since then he has had varied experiences. The glands enlarge at times of stress, and again quiet down with rest and open-air life. Last October, at a time when he was working very hard professionally, he consulted another medical man during my absence, and had operations on isolated glands, and in addition treatment by the *x*-rays. There was not much benefit, and there were some ugly scars.

Present condition: The patient came to me about the end of April, asking to have all the glands on the right side removed, as I had done on the left side some years previously. He was very hard pressed with work and wished to get back as quickly as possible. The glands on the right side of the neck from mastoid to clavicle are enlarged to such an extent as to form unsightly bosses. They have never been so bad before. In addition his appetite is poor, and he has a chronic morning cough and morning spit. Evening temperature 99.2°. His nasal respiration is imperfect. I advised against operation and in favor of nasal insufflations. Patient continued at his work during the whole time of treatment. April 30 nasal props were inserted and nasal respiration established. The props were used intermittently during treatment, which lasted from May 2 to June 28, and consisted of insufflations of mgm. 1/12 of tuberculin BE into alternate nostrils three times a week.

At the latter date the patient's condition was as follows: There were only three slightly enlarged glands to be felt. Temperature normal. Cough practically disappeared. Chest quite dry. General vitality much improved. Gain in weight of 5 lbs. Nasal catarrh also improved. Appetite excellent.

The treatment saved the patient an operation for which he was distinctly unsuited on account of his general condition. The result has far excelled that obtained by former methods.

Case III.—Mrs. D., age 29; housework; three children, aged 6, 4 and 2 years respectively. Ten years ago she had a bad cold on the chest. Her medical adviser told her that the lung was slightly affected. Before the confinement with her second child, four years ago, she had a cough. Before the confinement with her third child, two years ago, she had a cough, with a touch of pleurisy. Just before Christmas she was laid up in bed with bronchopneumonia. When first seen, on May 10, she had been ill for ten days. Purulent expectoration. Appetite very poor. Dullness and crepitations over both apices back and front, extending well below the clavicles. Slight pleuritic effusion left base. When first seen she refused to go to bed, but was compelled to do so on May 15.

May 16, 17, 18, 19 insufflations of mgm. 1/12 of tuberculin BE. Subsequent highest temperature recorded 99.2°. From May 29 to June 13 an insufflation of mgm. 1/12 every second day. June 13 general condition very satisfactory. No cough. No sputum. Appetite good. Temperature normal. Still a little dullness and a few crepitations at left apex. Advised to take fourteen days' holiday in the country. June 29: Has returned from country with a gain of 2 lbs. in weight and feeling splendid. Left apex better. Right apex quite clear.

From June 29 to July 10 insufflations of mgm. 1/10 every second day in alternate nostrils. Improvement is continued.

Although the area of the lungs affected was very considerable, the preliminary insufflations enabled me to give a good prognosis. This was confirmed by her past history and the result. In other words, she has a considerable natural resistance, which is in correspondence with the character of her nose and nose breathing.

Case IV.—P. N., male, age 46; general agent. He has been an energetic, wiry man engaged in many pursuits. I operated on one of his children four years ago for tuberculous glands in the neck. Patient six months ago began to suffer from general malaise and at last did not care what happened. Is taking brandy to pull himself together. Has had a bad cough with purulent sputum for last month. Also wheezing like asthma. Pains over apices of both lungs. He looks thin and tired; is 14 lbs. below his normal weight. There is considerable dullness over both apices. Suffers from morning cough with purulent sputum. Loss of appetite, debility and malaise.

May 19, props inserted. They were worn intermittently, but fairly well, during treatment. Patient was not laid up and followed his usual occupations. On May 21, 24, 26, 28 and 30 insufflations of mgm. 1/12 were given. The note on May 30 reads: Condition satisfactory. Vomiting and sinking at stomach better. No need for so much brandy. Sleeps better. Appetite better. Cough less and more mucous. Treatment by insufflations three times a week was continued through June and on July 10 the general condition was thoroughly satisfactory. Patient had regained his old "vim," was forceful rather than erratically energetic. Cough practically gone. Appetite good. A very slight gain in weight of 1 lb. No need for brandy. Nasal catarrh much better. No longer morning cough. Sleeps well. There was a little setback during treatment in the shape of a bad cold, when the patient did not feel so well for a few days. He volunteered the statement that formerly he always had to go to bed, but that this time he felt still able to keep about.

In conclusion I will quote a paragraph from Professor Adami's "Pathology," for it explains succinctly the *raison d'être* of my method of treatment. Professor Adami, in discussing tissue susceptibility, comes to the following important conclusion, and writes: "In infection, the body is never involved as a whole. Coincidently with the growth of the specific germs in individual organs, there tends to be a reaction to and destruction of the same in other parts."

Hypophysis Lesion in Dercum's Disease. — Exposel describes a case of adiposis dolorosa with asthenia and neurasthenia in which with proved lesion of the hypophysis there were also symptoms pointing to this organ. The Fröhlich syndrome was in nowise suggested. The author assumes that a lesion of the posterior lobe so modified the combustion that a deposit of fat resulted. The case has been made the subject of a graduation thesis by Dr. Monte Serra.—*Brazil-Médico.*

REPORT OF TWO CASES OF MULTIPLE KELOIDS.*

By J. E. LOPEZ-SILVERO, M.D.,

HAVANA, CUBA

DERMATOLOGIST OF THE TAMAYO DISPENSARY.

In the broad chapter of skin diseases due to the hypertrophy of the cutaneous tissue there is one that by its strangeness and clinical interest is worthy of attentive study. I am referring to the multiple keloid.

The first case is one in which the new growths appeared after a generalized fununculous acne. The second case was different in its origin.

Case I.—M. Crespo, white, male, 22 years of age; occupation, milkman. His father complained of vitilige and died at an advanced age; he has three brothers in apparently perfect health.

During his early life his health was good with only a suspicion of helminthiasis. At 18 he had an attack of sebaceous acne on the face, signs of the disease being still evident. His present trouble dates from 1910. It began with a generalized furunculosis of the back, arms and breast, accompanied with great itching and presenting the appearance of real pustules, persisted for a considerable time and on disappearing left rounded scars, punctuate in some places, elongated in others, of a whitish color and slightly preeminent. These scars continued growing slowly, changing in color, acquiring a reddish aspect till they took the present appearance.

Examination of the skin shows the following condi

Fig. 1.—Case 1, back view.

tion: In the iliac-to-rib region, on the left side, there are irregular patches of a brownish color. On the back there are old scars, rounded and elongated, that contrast strongly with the normal color of the skin. The hair is scanty. The digestive, respiratory, genito-urinary and circulatory tracts are normal. Nervous system shows normal sensibility and reflexes. The patient does not drink or smoke.

Case II.—R. Hernandez, male, negro, 31 years of age. In his infancy he had measles and chicken pox. At 21

Fig. 2.—Case 1, enlarged view of back of shoulder region.

he fought in the War of Independence and while in the army had an attack of parotiditis and one of pneumonia. Since then he has not been ill.

Four years ago he had a little furuncle in the suprahyoid region, accompanied by others that took a sycosis aspect, with a formation of a cyst that suppurated and was operated upon in the Hospital Mercedes. After this operation the other furuncles followed an identical course. They were treated by an electric-cauterization which was followed by the formation of fibrous scars. Two years ago he had a seborrheic acne of the sternal region and from each scar a keloid was developed. There are similar lesions to the inner side of the right mammary gland and clavicle, and another of rounded form and of corrugated surface just above the umbilicus.

Physical examination shows a well developed man, 137 pounds in weight. In the suprahyoid region the hair emerges from the borders of the connective tissue of the new growth. Digestive, circulatory, respiratory, urogenital, and nervous systems present nothing abnormal.

We will now note the features of the lesions peculiar to each case.

Case I.—The special features of the lesion in this case are the following:

1. Its symmetrical aspect. This can be observed especially in the third upper of the external and lateral side of the arm.

2. The confluence of the keloids. This can be seen in the sternal region, where each little new growth corresponds to a furuncle scar, which tends to extend in the neighboring tissue, forming a uniform mass; in early stages can be seen the apex of the furuncles, but as the process continues fibrous tissue is developed, forming a preeminence that varies in height from 2 to 20 millimeters.

*Read before the Sociedad de Estudios Clinicos de la Habana, February, 1916.

3. Its reddish color that contrasts with the color of the surrounding skin.
4. Its presence in an individual of the white race.
5. Its multiplicity, 374 in number.
6. Its origin in scars of generalized acne.

CASE II.—The following are the characteristic appearances in this case:

FIG. 3.—Case 1, front view.

1. The size of the keloids. The suprahyoid lesion is of considerable size, extending from lobule to lobule.
2. The small number of the growths.
3. The hardness of the lesion that gives it a woody feel.
4. In this case the lesions appear in the usual locations.
5. The conservation of some of the hair follicles of the chin imprisoned by the connective tissue of the tumors.
6. The origin of the lesion.

Wilson,[1] Schwimmer,[2] De Amicis,[3] W. G. Smith,[4] and Vidal[5] have reported similar cases of multiple keloid.

The etiology of this condition is unknown. Some authors give a tuberculous origin, for the following reasons: (1) The coexistence in the same subject of tuberculous lesions and keloid growths. (2) Its frequency in the black race, where tuberculosis is so common.

In neither of my cases was I able to find tuberculous signs. In the second case the patient had suffered from pneumonia, but disease had not left any signs denoting chronic condition in the lungs. The von Pirquet cutireaction was negative in both cases.

Histopathology.—The growth commences in the corium by dense bundles of fibrous connective tissue, rich in blood vessels. The blood vessels in the neighborhood of the keloid are affected; this explains why the growth recurs after its removal or excision; they are surrounded by spindle-shaped nucleated cells that are concerned in the keloid formation.

Formerly only two varieties of keloid were recognized: (1) False keloid, scar keloid, secondary keloid, and (2) primary keloid, ideopathic keloid, spontaneous keloid or true keloid. According to Unna,[6] however, this second form of keloid does not exist. The reason why the sternal region is the most frequent place for the so-called spontaneous keloid is because that region is the usual site of the dermatitis seborrheica, which precedes the development of fibrous tissue (Stelwagon[7]).

According to the histological structure Kaposi[8] divides keloids in three classes: (1) Spontaneous keloid. (2) False keloid or keloid developing on a scar, and (3) Hypertrophic cicatrix.

In the first class the epidermis and the papillary layer of the corium are not affected; in the hypertrophic scar the papillæ are destroyed by the growth or by traumatism; and in the false keloid both lesions are commonly associated.

Notwithstanding this classification based on the histopathology of keloid recent studies show us that there is not sufficient differentiation in the histological elements of the tumor to warrant such a division (Heidingsfeld[9]).

The modern theory of the etiology of keloids put forward by Bruntz and Spillmann[10] is that the passage of the leucocytes irritates the connective tissue elements, with proliferation and fibrous tissue formation as its consequence.

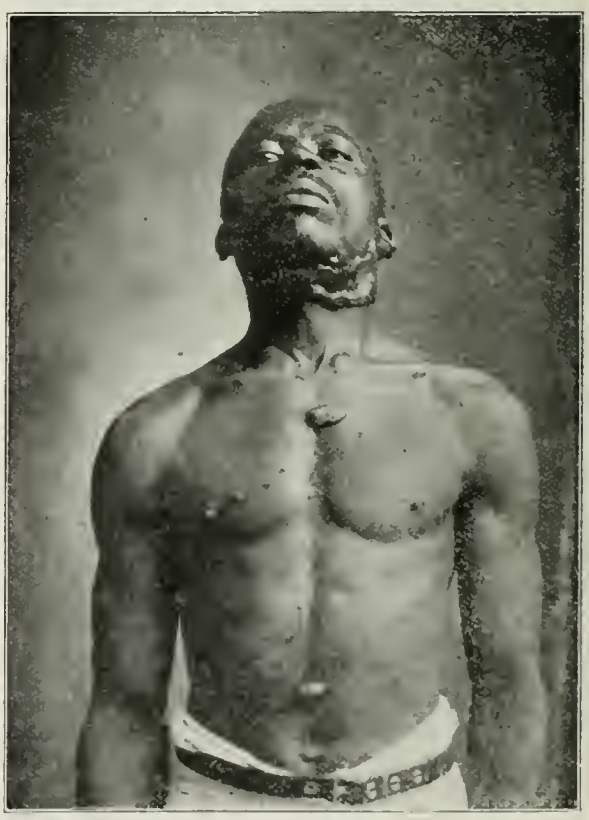

FIG. 4.—Case II.

Here in Cuba I have seen many cases of keloids in individuals of the black race, so I do not consider this malady so rare among us as many think.

In the times of negro slavery the punishments

of the slaves were terrible. Whipping constituted one of the principal penalties, and in the scars made by the lashes keloid often developed (Henri Dumont[11] and Manuel J. Castro[12]). The same occurred in the cicatrices of smallpox pustules (Galvez[13]).

Differential Diagnosis.—(1) From fibroma or molluscum fibrosum, by the normal appearance of the skin; by the pedicle of the molluscum, and its free movability.

(2) From framboesia, pian or bouba, by the general disturbances of this disease, the eruption of papules, and its transformation in papillomatous nodules that develop in a cauliflower form.

(3) From circumscribed scleroderma or morphea, by the stiffness, rigidity, and induration of the skin, nervous disturbances, etc.

(4) From the commencement of a malignant new growth, by the progress of the case, although it is to be remembered that a malignant neoplasm can originate in a keloid.

Prognosis.—It is a very rebellious disease. In some cases after a longer or shorter period keloid tends to diminish and sometimes disappear spontaneously (Hutchinson[14]). In others no change is observed, except in old keloids in which constant irritation may result in a malignant change.

Treatment.—Local: The continuous application of salicylic, ichthiolated, or mercurial ointments can be recommended in some cases. A solution of creosote, 5 grams, in olive oil, 25 grams, injected into the base of the tumor, sometimes gives good results (Marie[15]).

Thiosinamine in 10 per cent. solution by injection locally has been recommended by Tousey,[16] Crocker and Pernet[17] as useful. Others have failed with the same treatment. The use of the remedy in my cases has not been successful.

Linear and punctuate scarifications followed by the application of an antiseptic dressing of wet or dry boric acid (Leloir and Vidal[18]) has given me better results.

The surgical method of excision generally has no effect, and recurrences usually take place.

Electrolysis has the advantage of diminishing the pain and size of the tumor; the same is true of the *x*-rays. With an electric current of 5 milliamperes the needle is introduced from the outside to the center of the keloid; and the operation is repeated, the punctures being made close together. This procedure may be successful when the growth is small.

The *x*-ray treatment combined with excision ultimately has given good results in keloid developed in scars following war wounds (Vautrin et Ettienne[19]).

The Finsen phototherapy is supposed to be at least as efficacious as the *x*-ray, but the light has less power of penetration. Vautrin recommends excision followed by radium or *x*-ray treatment.

THE MASTIC REACTION ON THE CEREBROSPINAL FLUID.

By E. R. SMITH, A.B.,

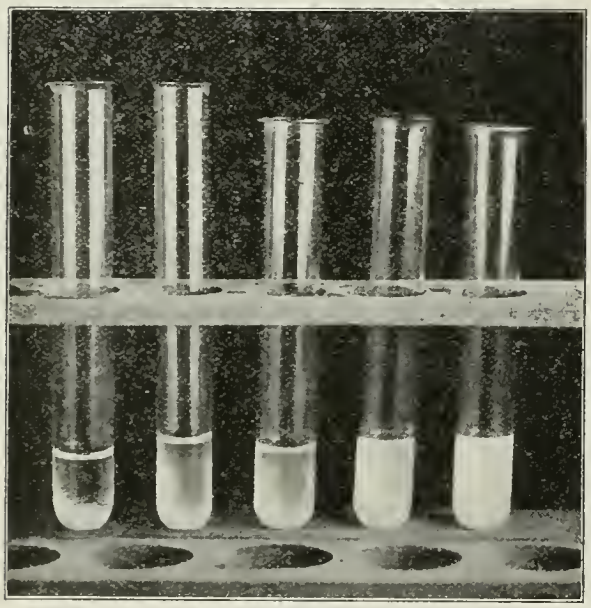
ANN ARBOR, MICHIGAN.

Recent investigations, particularly those of Novy, in the chemistry of colloidal substances have shown that it is probable that the physical properties and condition of these substances have a profound effect on their biological activities, and also that these conditions are very labile. Both of these factors should render their study interesting and important. Although colloidal substances have been used to some extent in therapy and chemical investigations of various natures have been made, the problems associated with their biological relations remain unsolved. But little use has been made of the properties of colloids in testing organic fluids. Lange first suggested the use of a solution of colloidal gold as a reagent for testing cerebrospinal fluid and many interesting and instructive results have been obtained from its use. It has been demonstrated that while not a substitute for the Wassermann reaction, it gives positive results with spinal fluids from cases of syphilis of the central nervous system and that some peculiarities of the reaction correspond fairly closely with the clinical aspects of the cases tested, *i.e.* the "curves" are different. Furthermore, it is determined that the curve is different and also fairly characteristic in certain non-syphilitic diseases of the central nervous system. This evidently affords a valuable means of positive diagnosis in doubtful cases. The difficulty in the preparation of the reagent is the chief clinical objection to the test.

In 1915, Emmanuel suggested the use of a mastic emulsion as a substitute for the gold colloid, the general principles of the test having been given by H. Sachs. This test has not attracted much attention (recent German literature has not been available). However, Cutting and later Lowrey have reported its use in asylum cases in this country. Emmanuel found that the reaction was positive in paresis, faintly positive in apoplexy, traumatic neurosis, and in one case of dementia precox, but negative in other cases of dementia precox and in functional cases.

*From the Clinic for Diseases of the Nervous System, Hospital of the University of Michigan, Ann Arbor, Mich.

The technique suggested and used by Emmanuel is as follows: A stock solution of ten grams of gum mastic in 100 c.c. of absolute alcohol is made. One cubic centimeter of this solution is added to 9 c.c. of absolute alcohol and this "insufflated" with 40 c.c. of distilled water. This gives an opalescent fluid. A 1.25 per cent. solution of sodium chloride is also prepared, which is put in five test tubes, one and one-half c.c. in the first and 1 c.c. in each of the remaining. To the first tube $\frac{1}{2}$ c.c. of cerebrospinal fluid is added. The content of the first tube is then thoroughly mixed and 1 c.c. of it is transferred to the second. The content of the second tube is likewise mixed and 1 c.c. transferred to the third and so on. None of the mixture of the fourth tube is put into the fifth, which acts as control, the extra c.c. from the fourth tube being thrown out. To each of the tubes there is then added 1 c.c. of the mastic emulsion and the tube contents are thoroughly mixed. The tubes are allowed to stand for from twelve to twenty-four hours. In all cases



Showing degrees of precipitation in Mastic Test. The tube on the left is a No. 4, complete precipitation. The tube on the right is a negative (control).

by this method the fifth or control tube is precipitated (a white precipitate with a clear supernatant fluid). In negative fluids the first four tubes are unchanged, the colloid remaining in suspension, but in positive cases some or all of the tubes are precipitated. Lowrey's results, using the same technique, were practically identical with those of Emmanuel. It would seem from these results that normal spinal fluids contain something, even though in high dilution, that prevents the precipitation of the colloid and this is apparently the theory on which the test is based.

Cutting found that the addition of a small amount of potassium carbonate to the salt solution prevented the precipitation of the mastic in the control tube, although the precipitation occurred in the tubes to which the spinal fluid from positive cases had been added, but not when normal fluid was tested. It may be inferred from this that the reason the mastic was not precipitated in the first four tubes in negative cases tested by the Emmanuel technique was because of the normal alkalinity of the spinal fluid that was added and that the precipitation of the mastic in positive cases was not due to the removal of the inhibiting substance, but was due to some additional substance which was present, since even though sufficient alkali is added to keep the control from precipitating, the positive fluid still causes precipitation. The results obtained by Cutting in asylum cases were sufficiently definite to suggest that the test might be useful as a substitute for the gold-sol. Being cheaper and much easier to prepare the reagent, the test is within the reach of any well equipped physician.

In order to be as useful as the gold-sol reaction, it is necessary that the precipitation occur in varying degrees in the different tubes in the series, as it does in the gold test, and that curves plotted from these tubes correspond to clinical syndromes and to the other biological tests. Other workers with this test have been content to report their findings as either positive or negative.

The technique that we have followed is that of Cutting, which is the same as Emmanuel's, with the important exception that to every 99 c.c. of the salt solution there is added 1 c.c. of a 0.5 per cent. solution of potassium carbonate. Made in this way the mastic is not precipitated in the control tube even though it is allowed to stand for days. The mastic is not precipitated in any of the tubes to which the spinal fluid is added if the test is entirely negative. With pathological fluids varying degrees of precipitation occur and in order to define these briefly we have divided them into four (much as the change of color in the gold-sol is divided into four or five degrees). One, denotes a milky fluid, loss of opalescence with a very slight precipitate; two, a distinct precipitate but a milky supernatant fluid; three, marked precipitate with slight clouding of the fluid; four, complete precipitate, clear fluid (see illustration). These changes are sufficiently definite to be easily recognized and a curve can be plotted from the results. We have usually employed eight or more tubes to obtain the full length of the curve. The mastic emulsion should be used freshly made, otherwise it turns a little milky and the change from control to a number one tube is difficult to determine. The spinal fluid may be allowed to stand for 24 or even 36 hours before being tested and will give the same curve as if tested while fresh (we have tested the same fluid on successive days and found the same type of curve, though after 36 hours the maximum change is not so great, *i.e.* the curve is flattened). Boiling the fluid before testing lessens the reaction, although it does not render a strongly positive fluid negative. Keeping the fluid at a temperature of 57° C. for one hour before testing does not change the result, although the precipitation in positive tubes takes place more rapidly than when the fluid is not heated. The presence of fresh blood in the fluid changes the type of the curve quite decidedly. We tested the clear spinal fluid and also some fluid obtained at the same puncture in which there was a slight admixture of blood caused by inserting the needle a second time with the trocar out. The specimen containing the blood gave a curve reading 12333210, whereas the clear specimen gave 44444210. In another case the same experiment gave: with the blood 24443000, without the blood 44321000.

The results of a series of tests are summarized in tabular form together with the diagnosis and the results of other biological and chemical tests on the spinal fluid.

It will be noticed that the reaction is positive, *i.e.* there is precipitation in some of the tubes, in all of the cases where it would be expected as a result either of clinical diagnosis or of the other findings. Both the gold-sol reaction and the mastic reaction are positive in multiple sclerosis. That the gold-sol reaction is positive in these cases has been pointed out by de Crinis and Frank. In one of the cases of multiple sclerosis in our table the diagnosis was confirmed by autopsy. The epileptic with positive gold-sol and mastic reactions probably had some organic disease of the brain, although its nature was not determined.

In case No. 29 in the table there was a history of syphilitic infection and intensive treatment, but at the time of our examination all findings were negative. The patient with multiple arthritis (No. 28) had an Argyl-Robertson pupil, but no other evidence of syphilis of the nervous system. She had not had antisyphilitic treatment and did not know of her infection. As the Wassermann reaction on the spinal fluid, the Nonne-Apelt reaction, the carbolic acid reaction of Pandi, and the cell count were all negative, it might be argued that the gold-sol and mastic reactions were the most sensitive of all tests for the involvement of the central nervous system and in view of the presence of pupillary disturbances this statement would seem quite likely.

Our results would seem to justify the conclusion that the mastic reaction is a valuable addition to the tests on the spinal fluid that are in general use and that information obtained from it is the same as that obtained from the Lange test.

Summarized Data.*

*The clinical diagnoses were made by Dr. Carl D. Camp without prior knowledge of the biological reactions. For the fluid in Cases Nos. 11 to 27, inclusive, I am indebted to the Clinic for Dermatology and Syphilology of the University Hospital (Dr. Udo Wile) where the clinical diagnoses in these cases were made also. The Wassermann tests and the gold-sol reactions on the spinal fluid were made by Dr. S. Ide in the laboratory of the State Psychopathic Hospital.

THE WASSERMANN REACTION AND PULMONARY TUBERCULOSIS.*

By JAMES S. FORD, M.D.,

LOOMIS, NEW YORK.

ASST. PHYSICIAN, LOOMIS SANATORIUM.

Two years ago one of our patients complained one morning that he had an uncomfortable feeling in his throat every time he ate or drank. Examination of his pharynx revealed three or four ulcerations about the size of an almond having a punched out appearance and covered with a nasty dirty gray membrane. There was also rather an offensive odor from them. Questioning revealed the fact that the patient, while in the Navy a few years before, had identically the same lesions which he said cleared up under muscular injections of some kind. A specimen of blood was obtained for a Wassermann reaction and this was reported as positive. An injection of neo-salvarsan was then given but before any results could be noticed from it, the patient left the sanatorium.

It then occurred to us that it would be a wise procedure to have a Wassermann test upon all of our new patients and this we have done in practically every case admitted during the past two years.

We thought in the beginning that this would bring to light a fairly good percentage of patients harboring a syphilitic infection, innocently or otherwise, but as time went on we discovered surprisingly few positive cases of lues and our figures are at decided variance with some of the other American observers. In the positive cases we found the histories absolutely unreliable, but by close questioning following the receipt of the laboratory report we have been able in all cases but two to get the patient to acknowledge his infection or else elicit a history pointing to a congenital type of disease.

From the very inception of this work we have never accepted as final evidence of syphilis one positive test but have always sent another specimen of blood for examination the following week and in many of the cases at odd intervals while the patient was under our care. In this way we fully believe that we have secured absolute proof, so far as the accuracy of the test can furnish it, of the presence of any syphilitic infection, but a case not showing a persistently positive reaction has been set down as non-luetic. The insistence upon more than one positive test before putting the stigma of syphilis on a patient may be criticized by some but I feel strongly that this is only fair to the individual.

Even though many serologists claim that tuberculosis will give a positive Wassermann reaction, our experience has been that it will not give these results persistently even when no antiluetic treatment has been instituted. Nor does it seem plausible that all our cases, who the first time showed a positive test, with four or five later ones negative, underwent a spontaneous cure of a spirochete infection. No less an authority than E. L. Keyes, Jr.,[1] cites cases of positive reaction in tuberculous individuals and gives the impression that he believes that their infection with the tubercle bacillus was the factor in giving this result. With all respect for so eminent an authority, I must disagree with him for our observations bear out the statement that not one single case of a straight infection from tuberculosis gives a persistently positive Wassermann. Our experience has been limited to about 330 cases and while the number is small, it is large enough to allow some deductions.

I will not go into detail as to the various steps of the test but will simply state that in all cases a cholesterinized antigen was employed and that in a large percentage an acetone insoluble antigen and plain alcoholic extract of guinea pig's heart were used as controls. Thus we believe that once again we guarded against every source of error in arriving at our ultimate results. It has been argued[2] that cholesterinized antigens are more sensitive and less specific than the antigen, not so fortified, and this is the reason given by some for obtaining a high percentage of positive reactions in definitely known non-syphilitic sera. Snow and Cooper[3] give as an explanation for positive tests that "as cholesterin originates as a cleavage product from destroyed tissue and, as in tuberculosis there is always going on destruction and necrosis, the body will react to it as to any other antigen by the production of antibodies and that these antibodies will, when the Wassermann test is applied, find the complement." However attractive the above hypothesis may be, our experience has shown us that within one week's time a three plus may be changed to a negative and remain so and within that same period of time no very marked change could possibly occur in the pulmonary lesion. It is my belief that even with a cholesterinized antigen a positive Wassermann will not persist unless there is an accompanying lues as well.

In the beginning of our work we were rather struck by the fact that practically all our laryngeal cases gave a positive result on the first test but on subsequent tests were all negative. For the past year we have not had a single throat case reported as positive although the same antigen and technic have been employed throughout. Our early results seem to parallel those of many other observers. In comparing our results with those of some other American observers we find that we have had a smaller percentage of positive tests that were really syphilitic as well as a lessened number of positive reactions that were given with non-syphilitic sera.

J. A. Lyons[4] reports 29, or 6.2 per cent. positive out of 471 patients and adds that the results with twelve, or 3 per cent., other sera were doubtful or unsatisfactory; Jones[5] of Seattle, reports 73, or 29

*Read before National Association for the Study and Prevention of Tuberculosis at Cincinnati, Ohio, May 10, 1917.

per cent., positive out of 251 patients coming to the public clinics. Snow and Cooper[3] report 20 per cent. of 290 definitely syphilitic and that 31 per cent. of their non-luetic cases gave a positive result, while Petroff[6] results show 82 cases, or 21.8 per cent. out of 376 gave a positive reaction when a cholesterinized antigen was used while only 9, or 2.4 per cent. gave the same result when an antigen minus the cholesterin was used. Our own results show that of 328 patients whose sera were tested 302, 92 per cent., gave a negative result on the first examination; 16, 5 per cent., that were one or two plus the first examination gave a negative result the following week and were always negative thereafter. In three, 1 per cent., sera, that were three plus the first examination were reported as negative two weeks later and remained so afterward while seven, 2 per cent., showed a three or four plus Wassermann persistently positive. In five of these seven cases we were able to elicit a specific history, while with the other two no amount of questioning could bring the slightest information that might lead to a clinical diagnosis.

Never have I seen a serum that was reported as four plus change without energetic antisyphilitic treatment being instituted and believe this degree of fixation to be very rare in straight cases of tuberculous disease.

In conclusion then, we feel that[1] only a persistently positive Wassermann reaction should make one certain of a diagnosis of syphilis in a patient suffering from pulmonary tuberculosis and[2] that a cholesterinized antigen, in our series, has made practically little difference in the ultimate results.

This work was carried on at Gaylord Farm Sanatorium, at Wallingford, Connecticut, and I take this opportunity of thanking Doctor David R. Lyman for his cooperation and also Mr. Ivy Hiscock, of the Connecticut State Board of Health, for the performance of these tests.

Leprosy in Italy.—In 1912 a census of lepers was taken in both continental and insular Italy. The Minister of the Interior then notified the local practitioners of the whereabouts of the disease and recommended that all new cases be reported. In 1916, according to Bordoni-Uffreduzzi, the most unfavorable aspect of the problem is the part played by returned emigrants who have contracted the disease in Africa and South America.—*Annali d'Igiene.*

OPERATIONS FOR HARELIP AND CLEFT PALATE.*

By W. C. GEWIN, M.D.,

BIRMINGHAM, ALA.

THERE are several different varieties of harelip and, according to T. W. Brophy, as high as fifteen varieties of cleft palate; there are, strictly speaking, four different methods of technique, with many variations, according to the operator's skill and ingenuity. These methods are: compression, which must be done in earliest infancy; flaps formed of bone and mucoperiosteum, according to Ferguson; flaps reversing operations introduced by Sir Arbuthnot Lane; and mucoperiosteal flap-sliding operations by the Von Langenbeck-Warren method.

Sir Arbuthnot Lane closes the palatal fissure by a reversion of the flap, not working with the bone at all; to follow this method exclusively with any great measure of success, the operator must have an expert acquaintance with this technique, and it must be remembered that correct speech in after life is one of the most important conditions. This is most difficult to procure without bony union of the hard palate

The operation by median suture and mucoperiosteal flap-sliding procedure, according to von Langenbeck, has won great favor; clefts of the soft palate are especially amenable to this method. Doubtless, if it is possible, it is best to wait until the patient is between two and three years of age, in cleft of the hard palate, the natural bone changes necessarily making it an easier operation.

The Ferguson operation includes the transplanting of the bone as well as of the soft parts. Doubtless a large degree of success may be met by using this method—when it *is* successful—by which we mean that, if an infection should occur, and the separated bone be destroyed, it would be a very serious matter.

Under the present technique I do not believe that the best results are to be obtained by the strict adherence to any one method—in the future we may perfect a way of operating upon all such cases, obtaining a uniformity of results, under the one technique.

It is generally conceded that the earlier in life the operation is performed the more advantageous it is for the production of good results; yet many adult patients are received and operated upon, the operation being followed by almost perfect results.

When we consider the physical discomfort of a baby afflicted with cleft palate and harelip, and his inability to obtain his nourishment properly, thus causing an under-nourished condition which invites various ailments, and that, if he survives the ills of his infancy, he is confronted by lessened physical and mental health and growth and the constant humiliation of his deformity, we have sufficient reason to advise an early operation.

The harelip should be closed in earliest infancy, and as soon after the healing of the wound as the surgeon considers advisable, the palate should receive attention. It is, of course, understood that the child must be in good physical condition, as compli-

*Read at the annual meeting of the Chattahoochee Valley Medical and Surgical Association, held at Warm Springs, Ga., July 10-12, 1917.

cations may occur even in the most favorable cases. There is not usually an accompanying hemorrhage, yet one of the large arteries may very easily be cut, and a most persistent leakage result. It is also very difficult to prevent the swallowing of blood, which may be followed by an alarmingly high temperature, most difficult to control.

In selecting the method to be used, it must be remembered that not only the immediate result of the operation is to be considered, but the effect that years of growth may have upon it. It is often possible to cover the palate fissure with tissue, but let us remember that even then the faculty of perfect speech may not be procured. Above all things, we should be careful to conserve all tissue that may be of use in the future growth of the patient; the preservation of the tooth germs should be most carefully watched. I do not think the various plates, wirings, etc., should be used if it is possible to dispense with them and still obtain the desired result, as in many cases the wiring itself may cause complications.

It is a sad fact that many cases are brought back again, and yet again, for reoperation. Our technique must be greatly improved, ere we may truthfully assure ourselves of our proficiency.

It is highly desirable to keep a continuous record of each patient after he leaves the hospital, to watch the child through its growth and development, in order to determine the success of our operation, for success can be measured only by the end results. We may be able, in this way, to correct our own personal defects of procedure.

I keep as nearly complete a record as possible, consisting of the history upon admittance, the description of the deformity, etc.; next, the method of operation, the immediate recovery, and the appearance of the wound at leaving the hospital. I also endeavor to keep in touch with the patient to ascertain his speech development and final formation of lip, palate, nose, etc.

This is the only way I have of fully determining the faults of my technique, and I am as keenly searching for my faults as I am searching for the virtues of the technique of other men, for it is only by eliminating our own faults, exercising our own ingenuity, and adapting to our own use, the best methods of other men, that we may hope finally to achieve the perfection we are striving for.

A COSMETICALLY PERFECT, BLOODLESS CIRCUMCISION.

By HENRY J. MILLSTONE, M.D.,

CHICAGO, ILLINOIS.

It will be noticed that in the treatment of a given disease where practically every drug in the category of therapeutics has been recommended, nothing seems satisfactory, so with our operation of circumcision.

Bevan states that "in order for a surgeon to launch himself into the literary field he must devise some new method of circumcision."

Though this was probably the first known surgical procedure, having its origin in prehistoric and biblical times, still daily someone "comes out" with another improvement, and those of us who constantly observe what are called adult circumcisions can realize then why we are still looking for some better method. I therefore owe no apology for submitting this paper, hoping that in so doing I have gone a step further toward perfecting this minor yet very important operation.

Probably the commonest operation used today is

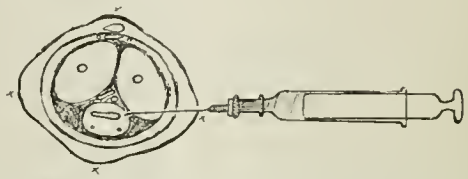

Fig. 1.—Method of nerve blocking. A bleb is inserted at the 4 points marked x, then the needle passed down to the urethra and withdrawn, depositing in its track about 5 drops of a ½ per cent. solution of novocaine.

the "clamp" operation, which is very unsatisfactory, as it really is a prepucotomy and not a prepucectomy. The other operation commonly used is the "cuff" operation, which can also be dispensed with; those who have done it know full well its disadvantages.

In reviewing the recent literature on the subject, Hessert[1] and Thornton,[2] whose operations are very much alike, approach very near to the performance of what might be considered a perfect circumcision. I have been doing this operation for about a year and it certainly offers many advantages over our old procedures.

An operation to be considered a perfect circum-

Fig. 2.—The mid-lateral cutaneous junction on each side of the prepuce is grasped with fine mosquito forceps and traction applied.

cision must fulfill the following requirements: 1. We must bear in mind that we are doing a prepucectomy and not a prepucotomy, so that the penis even in its flaccid state should not have a large fold in the "gutter" of the corona.

2. We must obtain a perfect cosmetic result. There is nothing more discouraging to the surgeon and disgusting to the patient than to find after about two weeks following the operation that the "corona" is crowned by a "beautiful cauliflower-like collar."

3. We must have perfect hemostasis. On account of the redundancy of the skin covering the penis, if

Fig. 3.—An 8 in. forceps is placed close on each side of the mosquito forceps and carried down to the corona.

there is any oozing it usually means the formation of a large hematoma, which furnishes a fertile field for infection.

4. We must preserve the frenum. As to how to dispense with the frenum. There has been much discussion as to the importance of the frenum, some

saying it has no importance whatever, others claiming it is of great importance. Estever and Chiappaori[3] tells us that the frenum contains highly specialized nerve endings and claim them to be the "terminals" for the erection center in the cord. They have some very interesting experiments and

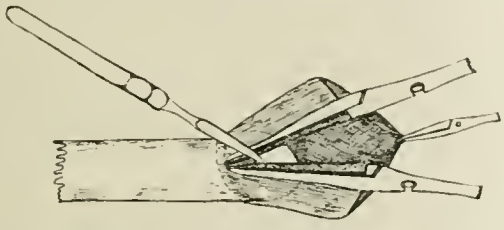

Fig. 4.—The mosquito forceps is released and a scalpel cuts between the two 8 in. forceps. Lateral traction is applied with the 8 in. forceps.

data to substantiate their argument and come to the conclusion that it is a structure which must be preserved, claiming "it is a spoke, essential in the erective cycle." An old axiom in surgery is "if you do not wish to injure a structure keep away from it," and if we are to give Estever and Chiappaori's work any consideration I think this structure should be handled with a certain degree of care.

5. We must have a short operation. The time element should never be a factor in accomplishing good work, still in this operation which so many men make an office procedure, using local anesthesia or gas, time should play some part.

Thus far all operations devised for circumcision have been by making a ventral and a dorsal incision into the prepuce.

Anesthetic.—This is an ideal operation to do under local anesthesia. I much prefer the nerve blocking method to the infiltration method, as it overcomes the marked edema and prevents distortion of the landmarks produced by infiltrating around the corona. About one inch from the corona in the midventral line a bleb of ½ per cent. novocaine solution is deposited under the skin and the needle is then thrust into the deep tissue to the urethra and about five drops deposited as the needle is withdrawn. The same is done in the middorsal line and on each side, as illustrated in Fig. 1. This, after the lapse of about two minutes, gives us a perfect anesthesia. Should one desire to employ a general anesthetic, on account of the rapidity with which the operation can be done, nitrous oxide will be found ideal.

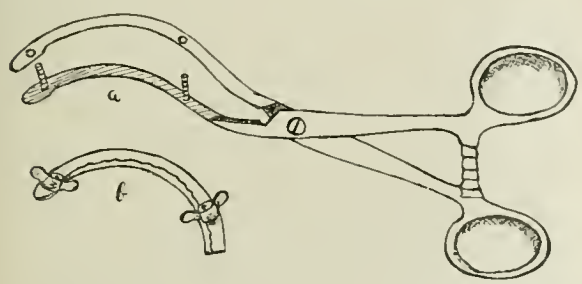

Fig. 5.—The prepuce clamp; (*a*) unlocked; (*b*) locked.

All rules pertaining to asepsis and antisepsis should be strictly observed.

Technique.—By means of mosquito forceps one grasps the midlateral point of the prepuce at the nucocutaneous junction on each side and applies traction. (Fig. 2.) An eight inch forceps is now passed along each side of each mosquito forceps and carried down to the corona and locked. (Fig. 3.) These eight inch forceps should be placed close together.

A scalpel now cuts between the two eight inch

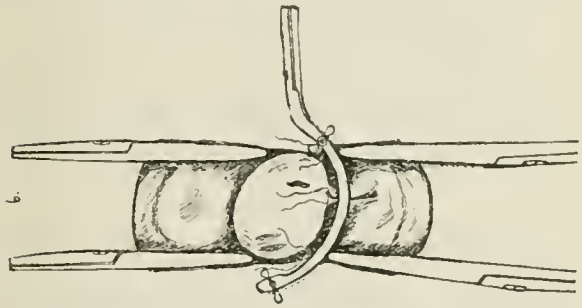

Fig. 6.—Shows anterior and posterior flaps made by cutting between the two 8 in. forceps on each side. The prepuce clamp is placed in the "gutter" of the coronal sulcus just in front of the two 8 in. forceps and locked. A through and through No. 0 chromic catgut suture is placed on each end of the clamp; a purse string suture takes care of the frenum.

forceps, giving us an anterior and posterior quadrilateral flap. (Fig. 4.)

Next the instrument which I devised (Fig. 5) and which I called a "prepuce clamp" is simply a stomach clamp curved so that it fits into the "gutter" of the coronal sulcus and has a lock on each end, so that it renders the tissues perfectly bloodless. This is placed just in front of the two eight inch forceps and locked perfectly tight. This instrument gives perfect coaptation between the skin and mucous membrane in the coronal sulcus. It is this point which is so essential in obtaining a perfect cosmetic result. (Fig. 6.)

A No. 1 plain catgut suture is placed as shown in Fig. 6, one at each end of the prepuce clamp, and tied. The best method I have found of dealing with the frenum is to place a purse-string suture around it. This procedure preserves all structures in the frenum and controls all ventral bleeding.

After the sutures are tied the scalpel cuts off the quadrilateral flap behind and close to the prepuce clamp, thereby leaving no tags. (Fig. 7.)

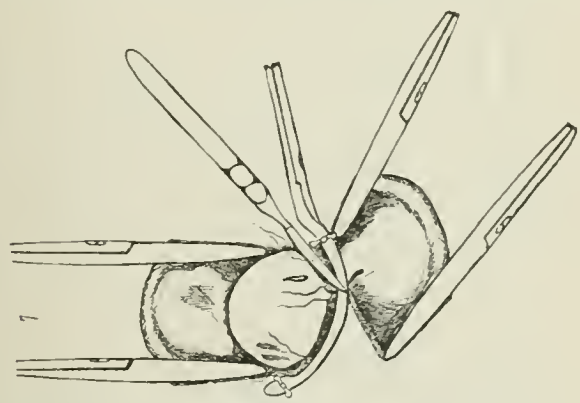

Fig. 7.—After the sutures are tied, the ventral flap is removed by cutting just behind and close to the "prepuce clamp."

The same method is used on the dorsal side. A half-inch bandage is now dipped in melted zinc oxide ointment and rolled around the line of incision a few times. A dry dressing is placed over this. This completes the technique of the operation,

which I am sure fulfills every requirement necessary for a perfect circumcision.

Its advantages are the following:

1. It gives a perfect cosmetic result, giving us perfect coaptation between skin and mucus membrane in the coronal sulcus and doing away with "tags."

2. The operation is practically bloodless.

3. It preserves the frenum.

4. It can be done under local anesthesia and is absolutely painless.

5. It can be made an office procedure and does not incapacitate your patient longer than 24 hours.

6. It can be done in about ten minutes.

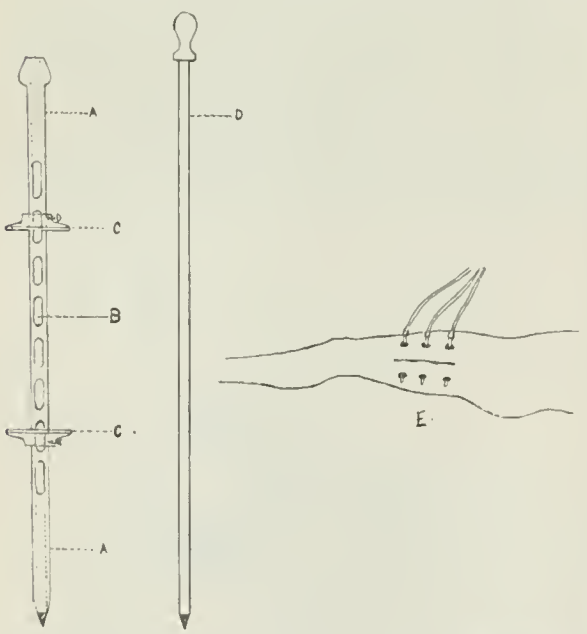
A CANNULA FOR USE WITH THE CARREL METHOD.

By E. E. Endicott, M.D.,
Jackson, Cal.

Since the advent of the Carrel method of irrigating large wounds, and the use of Dakin's solution, the decrease of the numbers of amputated limbs on the war front is simply marvelous. The virtue of the method depends upon a thorough and continuous irrigation with a non-irritating antiseptic.

It has occurred to the writer that the technique, while meritorious, is susceptible of improvement or modification.

The following drawing and description are presented for this purpose and for want of a better name the apparatus is called the apposition-irrigating-cannula. It consists of a large-sized fenestrated cannula with trocar, varying in length to suit the individual case.



Irrigating cannula fo rantiseptic wound treatment. A, A, cannula; B, fenestra; C, C, adjustable aluminum pads with set screws; D, trocar; E, three cannulæ applied to wound.

The cannula is fitted with adjustable aluminum pads, one inch in diameter, held in place with thumb screws.

After the wound is enlarged and cleansed, the cannula with trocar is introduced through the depth of the wound, its points of entrance and exit being through healthy tissue. The walls of the wound are brought into perfect apposition and held so by the adjustable aluminum pads.

The trocar is now removed, and the cannula connected with the apparatus supplying the Dakin or other solution. At each dressing the trocar is passed through the cannula to clear its lumen and insure a perfect flow of the antiseptic.

This method does away with deep buried sutures, insures perfect irrigation, approximates the walls of the cavity, and the aluminum pads distribute the traction over a greater surface than in other forms of sutures.

Medicolegal Notes.

License to Practise Osteopathy.—The Montana statute, Rev. Codes Sections 1594-1606, provides that every person who practises osteopathy in the State must secure a license from the State Board of Examiners, and provides a penalty for violation of the statute. Section 1605 defines the practice of osteopathy, and subdivision "b" provides that nothing in this section shall restrain any legally licensed physician or surgeon in the practice of his profession. Section 1597 provides that the secretary of the board of osteopathy examiners may, upon examination, grant a certificate to practise osteopathy until the next meeting of said board, when the temporary certificate shall expire. The practice of medicine and surgery is regulated by Sections 1585-1593. Section 1591 defines "practising medicine or surgery," and then provides that the section shall not be construed to restrict any legally licensed osteopathic practitioner practising under the laws of the State. In a prosecution under the statute for practising osteopathy without a license, it was held that the provision in Section 1591 does not permit an osteopathic practitioner to practise surgery without a certificate from the State Board of Medical Examiners, and the provision in Section 1605b does not exempt physicians or surgeons from the operation of the statute prohibiting the practice of osteopathy without the required license, and neither of the compensating provisions are "exceptions" within the meaning of that term as applied to statutory construction, as an "exception" takes out of an engagement or enactment something that would otherwise be a part of the subject-matter of it.—State vs. Wood, Montana Supreme Court, 165 Pac. 592.

Unauthorized Prescription of Intoxicating Liquors.—In a prosecution of a licensed physician for issuing a prescription for whiskey without good reason to believe that one to whom it was issued required it as medicine, in violation of a city ordinance, evidence that the defendant had during six weeks over which the inquiry extended given 673 prescriptions for intoxicating liquor, the usual quantity prescribed being one quart, that he issued as many as forty in a day, and examined the prosecuting witness very superficially when the prescription set forth in the complaint was given, was held sufficient to justify a finding of guilty.—City of Everett vs. Cowles, Washington Supreme Court, 166 Pac. 786.

Waiver of Privileged Communications Privilege—Under the Michigan statute prohibiting disclosure by a physician of information imparted to him in his professional capacity by a patient, with an exception in case of a contest of the will of such patient, the Michigan Supreme Court holds that a waiver by an insured, in a fraternal benefit policy, of a privilege relating to the disclosure by attending physician of information obtained while acting as such, was inoperative to render a physician's testimony admissible in a suit on the policy.—Gilchrist vs. Mystic Workmen, 163 N. W. 10.

Military Medicine.

A COUPLE OF POINTS IN WAR SURGERY.

THE surgical experience gained in the present war has not been, on the whole, particularly encouraging. At any rate, sepsis at the various fronts has been more or less rampant. Col. T. H. Goodwin of the British Army Medical Service, writing in the *Military Surgeon* for September, 1917, says that the antiseptic treatment of wounds has proved somewhat disappointing. He states that adequate drainage and mechanical cleansing form the first essential steps and adds that the following antiseptics have been found useful: (1) Two per cent. iodine in spirit; not advisable for interior of large wounds. (2) Carbolic acid, 2½ to 5 per cent. (3) Lysol, a dram to a pint. (4) Hydrogen peroxide, 5 to 10 volumes. (5) One per cent. watery solution of picric acid for multiple superficial wounds. (6) Flavine; this antiseptic promises extremely well, as it appears to have powerful antiseptic action with but slight toxic action on the tissues.

With regard to gas gangrene the following treatment is recommended: Free incisions; removal of dead tissue; thorough cleansing of the wound; hydrogen peroxide; drainage. If hand or foot is warm one should not amputate. If it is cold and insensitive, one should amputate at once, if the general condition of the patient permits.

As for wounds of the abdomen the writer points out that a large proportion of men shot through the abdomen die on the field. Wounds of the small intestines are usually multiple. A primary operation may reasonably be performed under the following conditions: (1) If seen within twenty-four hours of injury and the general condition is good; (2) if only a small part of the whole abdomen has been traversed; (3) if it is certain that the peritoneum has been opened; (4) if the patient's condition is becoming worse; (5) if the conditions for operation are satisfactory; (6) if the pulse is becoming more rapid or the rigidity of the abdomen is increasing.

EVOLUTION OF GENERAL PARALYSIS AMONG TROOPS.

IN theory an officer's duties on the fighting front should be well calculated to accelerate the evolution of paresis. Mignot, a French psychiatrist (*La Presse Médieale*, August 23) has found that in peace times only about 8 per cent. of paretics die of their disease within a year. Since August 1, 1914, the Charenton Asylum has admitted 145 paretics, and during the three years of the war 50 of this number have perished. The privates and non-commissioned officers, however, make but a temporary sojourn here, so that the author can only submit details of the cases of commissioned officers who remain in the asylum. These are carefully distinguished from the lay patients who always made up the great majority of permanent incumbents. He has completed notes of the cases of 16 officers who did not fight at the front, and of this number but one died within the first year of evolution of the disease. The average duration was thirty-six months. He also has notes of the cases of 11 officers who had either fought or had been on duty in the fighting zone, and in these the disease developed within a year in no less than 7 (4 of these within 6 months). The average duration of evolution in these 11 patients was but 10 months. This rapidity of evolution does not only mean very early decease but complete absence of any tendency to remissions while the socalled terminal symptoms appear at a very early date. Ordinarily interning paretics is followed by temporary arrest or improvement of symtoms, but in the author's material only 4 officers who had been in the fighting zone showed any such conservative tendency. Clearly the fatigue, the emotions, and traumatisms of warfare exert a very bad influence on the course of the disease.

Gunshot Wounds of the Peripheral Nerves.—Injuries of peripheral nerves have occurred with great frequency during the present war owing to the use of projectiles of high velocity. It is obvious that their successful treatment is of the highest importance in the prevention of permanent disabilities of the most serious kind. Lieut.-Col. J. Michell Clarke, writing in the Bristol *Medico-Chirurgical Journal*, summer number, 1917, says that we are not yet in a position to make positive statements as to what the ultimate results of nerve injuries and the operations undertaken for their relief will be.

The nerves most frequently affected are the musculospiral, median, and ulnar in the arm, the sciatic, and especially its external popliteal branch, in the leg. Injuries to the brachial plexus are also common.

A nerve may be completely divided; when this is so there is rarely a clean cut through it, but more often destruction or obliteration of it for a considerable distance, from one to several inches; or it may be partially divided; or it may be injured by compression in scar-tissue by callus, by fragments of bone, by a lodged bullet or portions of clothing, by a traumatic aneurysm, by bruising, or concussion.

It is important to remember that perineural scars and adhesions, though conspicuous at operation, may not be responsible for blocking the passage of impulses, but that this may be due to concomitant intraneural hemorrhage, fibrosis, or molecular changes following concussion. Trotter and Davis have shown the intolerance of the ordinarily isolated nerve tissue to the contact of connective tissue, and that the active outgrowth of nerve fibrils of a divided nerve is a response to the contact of non-nervous tissue which, on its part, forms a tough fibrous capsule around them and prevents their further extension: this may lead to irritation of the nerve and hypersensitiveness.

The location of the injury to the nerve rests on anatomical data and on the course of the projectile, aided, perhaps, by the *x*-ray. In multiple wounds the diagnosis of the one causing the lesion is based on anatomical considerations. The extent of damage to the nerve is estimated by investigation of motor and sensory paralysis, muscular wasting, pains and hyperesthesia, trophic lesions, and electrical reactions, and all of these symptoms which are present should be compared and the diagnosis

based upon the full results. There is no short cut to diagnosis. Many consider that sensory changes give more important information as to extent and progress of the lesion than motor paralysis or electrical reactions. It has been claimed that in incomplete division of a nerve the area of loss to protopathic sensation is greater than that to epicritic sensation, and that the borders of the respective areas approach and recede or cross each other. This is not yet established, but it is certain that the distinction between complete anatomical division of a nerve and physiological blocking of it by involvement in scar tissue cannot always be made. Pains and hyperesthesia signify partial injury of a nerve. When these gradually disappear and give place to analgesia and tactile anesthesia compression of the nerve by scar tissue, callus, etc., is probably taking place.

Hysterical anesthesia of the sleeve, glove, or stocking type may be present as a complication of peripheral nerve injuries, generally in partial ones. In gunshot wounds, however, especially in those of plexuses, the symptoms are often very complicated, and the sensory loss may not at first correspond with the known distribution of the nerves and may resemble hysterical anesthesia, but after a few weeks the picture partially clears up leaving a residual loss in recognized areas of nerve supply. The severe forms of trophic disturbance, such as deep and intractable ulcers, usually occur in complete division of a nerve, the milder forms in partial lesions.

With regard to electrical reactions of damaged nerves, it may be said that such reactions give no information as to what is going on in the nerve at the seat of injury. Their most important function is to decide whether there are any excitable fibers peripheral to the injury. When all have been lost voluntary power usually returns before the muscles respond to faradism or the condenser.

As to treatment before operation can be done (1) The wound must be soundly healed, and (2) there must be a sufficient interval after the injury before exact diagnosis is possible, partly because characteristic signs of division of a nerve take time to develop, and partly because in most cases of gunshot wounds of nerves the immediate paralysis is of greater extent than it remains permanently.

While waiting preliminary treatment must be carried out. This consists in wrapping the limb up warmly; in placing it on a suitable splint to keep the paralyzed muscles relaxed, a point of the greatest importance; daily gentle massage and movements, during which the paralyzed muscle must he kept relaxed, and electrical treatment by the passage of a constant current, or condensed discharge, rhythmically interrupted by a metronome and just strong enough to cause a contraction of the muscle.

It is desirable before operation to give a prophylactic dose of tetanus antitoxin, as tetanus may develop after operation is undertaken, even some months after the original injury.

Operation is advisable (and the earlier it is done the better are the results, as a rule): (1) In case of complete division of a nerve; (2) in incomplete lesions; (a) where the condition is stationary with a definite residue of paralysis after three to four months, (b) where improvement has begun but stopped abruptly, with signs of compression of the nerve by scar tissue, callus, etc.; (c) where there is great pain, not relieved after some weeks' careful treatment; in such a case the nerve should always be explored for pieces of bone, foreign bodies or shreds of clothing may be found in the wound, and (d) in cases of long standing with intractable trophic lesions, for even if no good to the paralysis results, the trophic lesions quickly heal.

In the majority of cases there is little difficulty in deciding whether operation is necessary or not. Even slight return of voluntary power negatives operation. In doubtful cases nothing is lost and often much gained by an exploratory operation.

In plexus lesions where several trunks have been divided, often at different levels with much resultant perineural scar tissue, accurate identification of trunks for end-to-end suture is often most difficult, and if it is found impossible, it is probably better to leave things alone than to do indiscriminate nerve crossing. Trotter advises early operation in cauda equina lesions in every case where there is the least suspicion of an element of pressure.

The postoperative treatment, and that of cases of partial division of nerves is the same as advised above in preliminary treatment, and should be continued daily until there is a return of voluntary impulses which may take weeks or years. In the lower extremity a walking machine must also be provided for dropped feet. After end-to-end suture of a nerve electrical treatment should not be begun for some little time and then with great care.

In all cases, especially in the early stages, care must be taken to avoid fatigue of the muscles by electrical treatment; the balance of evidence is that contractions due to electrical stimulation are beneficial in the stage of regeneration, but have no effect on muscular wasting as to results. Cases of nerve concussion should recover within four to six weeks; partial division of a nerve should go to complete recovery in several months.

Intoxication with Asphyxiating Gases and Its Treatment.—While this subject has pretty well crystallized out in literature there is always the possibility that the introduction of a new gas on a huge scale may necessitate a revision of our knowledge. The subject has been comparatively simple only because chlorine has been the one gas used in actual work. All others seem never to have made good in extensive try outs, with the possible exception of lacrymating gas supposed to be or contain bromine.

An article by Colard and Spehl in the *Archives Médicales Belges* for July discusses an experience with gas during the present year, probably in the spring offensive, of a Belgian command on the Yser front. Nothing is said of the nature of the gas used although delivery from cylinders was the method used; but all points to the fact that chlorine is still employed to the exclusion of all other substances. The respiratory phenomena are those chiefly in evidence in gassing and the grouping of cases depends on the gravity of these symptoms.

The authors eliminate the cases which end in rapid death with the brief symptom picture of intense cyanosis, foaming at mouth, and abundant vomiting of blood. With these out we have two principal syndromes, viz., acute asphyxia and caustic tracheobronchitis.

In victims of acute asphyxia there are no evidences of profound general intoxication, as in the fatal cases. The symptoms are local, and their severity lies in the fact that a large enough portion of the respiratory surface is involved to produce asphyxia, as shown by marked cyanosis and characteristic pulse and respiration. The victims of caustic tracheobronchitis do not suffer from asphyxia, for there is enough breathing surface to guarantee hematosis. In this group the patient's life is not necessarily endangered.

In the asphyxia group, which is the least numerous, there is a persistent cough with a sensation of laceration of the chest. But after the passage of the gas-wave there is sometimes relief, which, however, is deceptive. Not long afterward the symptoms increase, and dyspnea, intense cough, and foamy expectoration indicate the presence of edema of the lungs. Upon arrival at hospital these patients are cyanotic and prostrated. The picture is too familiar on all fronts to be detailed here, and has been fully described again and again with all the graphic realism of the old clinicians, when in the absence of clinical material they sought to visualize clinical pictures. There are important distinctions here, for the badly gassed subject may show a forced, labored, and consequently slow respiratory rhythm, while the man not so badly off breathes rapidly in a compensatory effort. In forced breathing the pulse may be suppressed or only enfeebled, irregular, and unequal. If these patients survive a certain cardiac rhythm follows in a few days which denotes a weakened myocardium and is manifested by a bigeminal, pseudo alternating pulse in which the arrhythmia is of extrasystolic origin. Here the excitability and not the contractility of the heart is prejudiced. In such cases the cardiac affection is shortlived and in five or six days the patient will be over the worst of his troubles. Auscultation gives moist, finely bubbling râles over all the lungs. In cases with recovery as to life caustic tracheobronchitis is the normal sequela.

As already stated the last named condition is often the primary manifestation. This is the secondary bronchitis of authors, which like the picture of acute asphyxia from edema of the lungs has been described to death. In the interest of simplicity the authors represent the two types of gassing (with survival) as follows: A—Caustic tracheobronchitis plus asphyxia (due to a certain degree of involvement of breathing surface) and B—Caustic tracheobronchitis without asphyxia. In other words the (aseptic) inflammation of the mucosa is present from the very start. This is a restatement of older accounts of gassing which made of bronchitis an inevitable sequela, developing after a period of latency.

Treatment of these cases shows some modification, for venesection and oxygen inhalation are the remedies *sine que non* for asphyxia cases. Blood is invariably taken from an arm vein to the amount of 300 c.c. in these subjects. This step may be repeated if advisable on the following day; and in certain cases more blood—up to 500 c.c.—may be taken at a time. That bleeding is indispensable seems well shown by the character of the blood flow, for the blood is tarry, blackish, and viscid. In bleeding, no attention should be paid to a low tension pulse. Oxygen should always be given early with the idea of recovery—not late to mitigate suffering in a doomed patient. The authors administer it by means of Wulff's bottles and a catheter introduced through a nostril.

Treatment of Gunshot Wounds of Peripheral Nerves.—Capt. Rendle Short writes in the *British Medico-Chirurgical Journal*, Summer Number, 1917, on the treatment of gunshot wounds of peripheral nerves. In cases of complete division of the nerve, with a bulbous swelling at the end of the upper segment, succeeded by a mass of scar tissue of variable thickness, and adherent to the surrounding tissue, the two ends of the nerve should be freed, and then the upper segment should be divided through the upper end of or above the bulbous swelling, so as to expose visible nerve bundles with no excess of interstitial fibrous tissue; when this is done the ends should be sutured with catgut. Some surgeons wrap the junction in Cargile membrane; others sometimes use a segment of the saphena vein, but often nothing is used.

It frequently happens that the ends cannot be brought together because of a gap of one or two inches. In such a case a bridge is formed of two or three pieces of internal cutaneous nerve taken from the upper arm, or by catgut strands; or the surgeon may resort to nerve anastomosis.

There may be a bulbous swelling on the nerve, adherent to the track of the bullet, and it may be doubtful whether the nerve fibers pass through it or are interrupted. In such a case one should stimulate the nerve electrically above and below the bulb. If, in the case of a small or medium-sized nerve, not the sciatic, any muscles supplied by it contract, the scar is freed and wrapped in a segment of saphena vein. If there is no response, one should excise the scar and suture. A large nerve, such as the sciatic, may show symptoms of a partial division, and at operation part of the nerve shows a scar. The best procedure is to take out a quadrilateral, including the scar, and, by splitting the nerve trunk up and down, to bring the two ends together, leaving the intact portion of the nerve undisturbed.

Finally, the nerve may be intact, but pressed upon by a bullet or by shattered bone. The treatment then is, of course, to remove the cause of pressure; but although this relieves pain at the time, it is unfortunately apt to return during the process of healing and prove very intractable.

Over 69,000 Men in the Army Medical Service.—The Medical Service of the Army now has a personnel of more than 69,000 men, compared with 6,600 just before the outbreak of the war. Nearly 13,000 officers had accepted commissions in the Medical Reserve Corps up to October 1, 1917. The Dental Reserve Corps now has over 2,600 commissioned officers and the Sanitary Corps about 240. The organization of the Surgeon General's Office has added sections on internal medicine; medical

officers' training camps; medical military instruction; psychology, neurology, and psychiatry; surgery, infectious diseases, and laboratories; head, eye, ear, mouth, and brain; military orthopedics; special hospitals and physical reconstruction; gas defense; food; office development and filing system. The Surgeon General's office now has over 500 clerks and messengers and more than 100 officers, compared with 140 clerks and messengers and 10 officers in March, 1917.

Professor Devine Heads Red Cross Bureau in France.—A recent cablegram announced the appointment of Edward T. Devine, professor of social economics at Columbia University and widely known as a social worker, as chief of the bureau of refugees and home relief, under the American Red Cross Commission in France. Some idea of the task with which Professor Devine is confronted may be gained when it is known that there are some 850,000 refugees embracing all classes and ages except able-bodied men in the departments of France outside the Seine. The Red Cross hopes to lessen the congestion and discomfort under which these people are living by providing better quarters and erecting temporary shelter when necessary. It is proposed to establish in cooperation with the French authorities health centers from which useful work can be done without compromising the self-respect and independence of those who accept it. Dr. Devine's work will be to coordinate the many voluntary relief agencies as well as the public relief authorities and arrange for constructive relief work for the victims of the war who have not yet returned to their homes.

"Psychological Gradings" for Soldiers.—Each man of about 160,000 in four National Army cantonments will be given an "intelligence rating," by psychological examination conducted by the section of psychology of the Surgeon General's office. Each man's record will be placed at the disposal of his company commander to assist him in picking men for promotion or for special lines of work. The various methods and tests used in making these examinations have been selected by a committee appointed by the Council of the American Phychological Association. The psychological staff which will make the tests at each of the cantonments will comprise four officers and six civilians.

Red Cross Units for Cities Near Camps.—Fifteen cities are now receiving the cooperation of the Red Cross in making the communities around the camps safe for the soldiers and in taking measures to prevent the spread of disease or epidemics. The three latest cities to receive such aid are Greenville, S. C.; Macon, Ga.; and Manhattan, Kan. Each of the sanitary units operates under the direction of an officer of the Public Health Service, and the field directors of the Red Cross Bureau of camp service have been made the business agents of the units. These units cooperate not only with the Public Health Service but with the State and local boards of health in establishing full and efficient sanitary organizations for the inspection of milk and water supplies, the control of infectious diseases, and the general sanitary inspection of the community. In the southern communities, considerable work is being done in the eradication of malaria bearing mosquitos in the vicinity of the camps.

Americans Win War Medals.—A cablegram from Paris announces that the Army Medical Service has awarded 136 war medals, 11 silver gilt, 50 silver, and 75 bronze, to workers in the American Hospital in Neuilly. The recipients of the medals are 37 men and 99 women, mostly Americans.

Discuss Problem of Disabled Soldier.—The Inter-allied Committee on Post-War Treatment of Permanently Disabled Soldiers met in London, England, on October 9, for a several days' session. The American delegates are Col. Birmingham, Major R. B. Osgood, Dr. Veditz, and Miss Grace Harper. There are similar delegations representing Great Britain, France, Russia, Italy, Belgium, Serbia, Montenegro and Portugal.

Association of Military Surgeons.—The twenty-fifth annual meeting of this association was held at the Medical Officers' Training Camp, Fort Benjamin Harrison, Ind., on October 8, 9, and 10, under the presidency of Surgeon General Rupert Blue, U. S. P. H. S. Among the papers on the program were: "Practical Medical Military Lessons of the War," by Col. T. H. Goodwin of the Royal Army Medical Corps; "Cooperation of the Civilian Medical Profession with the Medical Services of the Government in Time of War," by Major Victor C. Vaughan of the Medical Reserve Corps, U. S. A.; "How Military Medical Services of the Government May Best Cooperate in Time of War," by Col. Louis A. La Garde, M. C., U. S. A., P. A. Surgeon H. B. Eaton, U. S. N., and Assistant Surgeon General W. C. Rucker, U. S. P. H. S.; "Medical Service on the Western Front," by Col. Charles Dircle of the French Army Medical Department; "Transportation of Wounded on the Western Front," by Capt. J. Gilmour, R. A. M. C.; "Trench Warfare," by Lieut. Henri Haye of the French Infantry; "War Neuroses," by Major Thomas H. Salmon, M. R. C., U. S. A.; "An Efficient State Medical Department," by Lt. Col. Jacob Frank, M. C., Ills. N. G. Addresses were also made by Surgeon General W. C. Gorgas, U. S. A., Surgeon General Rupert Blue, U. S. P. H. S., president of the association; Surgeon Wm. Seaman Bainbridge, U. S. Navy, R. F.; Col. T. H. Goodwin, R. A. M. C.; Major Jos. C. Bloodgood, M. R. C., U. S. A. The election of officers for the coming year resulted as follows: *President*, Medical Director George A. Lung, U. S. N.; *First Vice-President*, Lieut. Col. Henry Allers, M. C., N. J. N. G.; *Second Vice-President*, Brigadier General Henry P. Birmingham, U. S. A.; *Third Vice-President*, Assistant Surgeon General J. S. Kerr, U. S. P. H. S.; *Secretary*, Col. Edward Munson, M. C., U. S. A.; *Treasurer*, Assistant Surgeon General W. Colby Rucker, U. S. P. H. S.

Camp Wadsworth Base Hospital.—The big base hospital at Camp Wadsworth is about finished, the contract calling for its completion by November 1. The hospital will consist of fifty-nine buildings, all connected with covered passageways, and giving accommodations for 1,000 beds. The cost of this hospital will be $450,000. Complaint is made, however, that thus far no provision has been made for installing a heating plant or for stoves, while provision has been made for heating all other buildings in the camp and for installing stoves even in the tents. The method for the disposal of sewage is also said to be defective.

MEDICAL RECORD.

A Weekly Journal of Medicine and Surgery.

New York, October 20, 1917.

A RAPID TEST FOR OCCULT BLOOD.

IN spite of the fact that the excessive growth of specialism in medicine has led to the custom of the average practitioner sending his specimens of all kinds to a laboratory for report, we should not assume unthinkingly that this is the ideal arrangement in all circumstances, but consider certain possibilities. The war, for example, threatens to deplete the ranks of our profession, just as it has done in other countries. It may be that the vast quantity of work of a laboratory nature to be done with the armies will thin out the ranks of technicians in civil life and at the same time the great demand for military surgeons will result in doubled work for the practitioners who are left. Many of these, especially if they do not live in large cities, will be obliged to do their own laboratory work.

To be sure, the average practitioner may say, "If it has to be done, I can do it." Perhaps he has had a good course in laboratory work in school, supplemented by more or less uranalysis, Widals, Wassermanns, and so on, in a hospital. All of this, of course, is valuable and forms a good background for the acquiring of proficiency in technique. But there is a great difference between the skilled and rapid methods of the trained laboratory worker and the laborious examinations of the general practitioner, working in an improvised laboratory, with a textbook propped up in front of him, and a large general practice dinning its demands into his ears.

For the benefit of such, an article by Warren T. Vaughan, in the *Journal of Laboratory and Clinical Medicine* for March, 1917, is applicable. As he rightly says, stool examinations are too much neglected. Lack of acquaintance with the methods, confidence in ability to diagnose without this aid, and the disagreeable nature of the details, all combine to cause the doctor to omit this diagnostic detail. And yet, if pressed for an answer, the practising physician can hardly refuse to admit that such an examination may often be of great value, and the cases are rare indeed where it would not throw some light on the patient's condition as a whole. Certainly, all gastrointestinal cases, as well as cancer suspects, should have stool examinations. The examination for occult blood, for example, although probably not familiar off-hand to the average practitioner, may be very useful in detecting early carcinoma, ulcer, or intestinal parasites. Barker states that as much as 5 per cent. of occult blood may be present without being recognized by the naked eye.

The first thing we think of is the guaiac test, but Vaughan calls attention to the advantages of the benzidin test which is generally considered too delicate for clinical use. He uses Wagner's "dry test," which consists in adding a few drops of mixture of a knife-point of powdered benzidin (an amount the size of a match head), 2 c.c. of glacial acetic acid, and 20 drops of a 3 per cent. solution of hydrogen peroxide to a little solid feces on a clean glass slide; a greenish-blue fading color is positive. The material for a slight variation of this test may now be obtained in very convenient form for the practising physician.

After exhaustive experience with this test, Dr. Vaughan concludes that it is the most reliable, as well as the most simple, rapid, and clean. It is not, he thinks, too delicate for clinical use. A negative result is more reliable evidence of the absence of blood than a negative guaiac test. Meat fibers, pus, and the usual drugs and food do not vitiate this test, and rare meat does so only if it has been taken in considerable quantity.

LEGISLATION IN VENEREAL PROPHYLAXIS.

THE State Commissioner of Health of New York asks the cooperation of the editors of the various periodicals and papers in spreading the knowledge of the law recently passed by the legislature requiring the contracting parties to a marriage to submit evidence of freedom from venereal disease for a period of five years next preceding the time of contract, or, if infected during that period, evidence of laboratory tests establishing cure. While New York is not the first State to pass legislation in this regard, it is the first of the States to realize that the enactments must be conservative, at least, in the beginning if the cooperation of the public is to be obtained. It must be realized that the more radical the act the more difficult of enforcement and the less that can be taken under the protective fold of such an enactment. The Wisconsin law made it obligatory upon every person contemplating marriage to submit to appropriate physical and laboratory examinations and even went so far as to fix the fee for such examinations. It is to be hoped that with the more conservative New York law more will be accomplished. Yet it is hardly to be expected that the mere presentation of certificates setting forth freedom from disease will be a guarantee against the consequences of such infections. Most instances of gonococcus infection in women who help fill the gynecological wards of the hospitals are not caused by acute infections in their partners but rather by chronic dormant and undetectable infections reactivated in the always fertile virgin soil of the female. The ophthalmias of the newborn are, similarly, caused by this reactivated infection in

the mother. Moreover, with intent to deceive the examiner the Wassermann reaction may be masked in various ways

The entire value of a law dealing with venereal prophylaxis lies not so much in the prohibition enforced as in bringing to the attention of everyone the significance of venereal infection to the parties contemplating marriage, the effect on their offspring, and the more indirect, but none the less important effect upon the nation as a whole. With this knowledge continually being brought home, measures for venereal prophylaxis will be more universally observed, and treatment more generally and consistently carried out. When once the gravity of these infections is impressed upon young adults, the solution of the problem of venereal infections will more nearly have been achieved.

BILHARZIOSIS.

In the *Journal d'urologie médicale et chirurgicale*, for August, appear no less than four articles on this subject. Diamantis of Cairo writes on modes of infection. Does the schistosomum enter the body by the mouth, the perineal orifices, or the percutaneous route? He supposes the second of these hypotheses. The parasite appears to inhabit the pelvic veins, which in turn receive blood from the cutaneous veins of the perineum. It is present in the veins of the bladder and rectum. In what manner is its entrance into these vessels effected? Doubtless by ablution, for the Mohammedan is obliged by his religion to wash himself a number of times daily. Any water will answer the purpose and it often happens that a number of men use the same water. The women, who are not compelled to bathe, seldom show the disease (sex ratio 1:20). Not over 5 per cent. of them bathe, and these never in common. This sex selection is not in force in young children nor in older women who have lost much of their early modesty, the latter being at its height in adolescent girls. Why is the bladder so often attacked while the rectum escapes? Perhaps because of the minute toilet of the penis and entrance of the worm into the region of the dorsal vein of the penis. This is the chief route of infection, although exceptionally penetration can occur anywhere on the surface.

The same author also contributes a paper on a new method of treatment of bilharziosis. This is none other than the use of emetine which, through its hemostatic, amebecide, and—in mouth infection—emetic properties, is admirably suited for combating this evil. The alkaloid should be injected into a vein in all cases.

Morel and Maldonado report four cases of endemic bilharziosis occurring in Paris. All were of the vesical type with cystoscopic and microscopic diagnosis. There is no successful treatment for localized, noninfectious, uncomplicated cases. According to these authors the emetine treatment is not only new but without any effect.

Diamantis and Lotsy also report briefly a case of early ureterovesical bilharziosis with radiographic diagnosis. The first diagnosis was ureteral calculus, and vain attempts were made to free it. Certain peculiar shadows in a radiograph caused suspicion of bilharziosis, confirmed by cystoscopy.

HOME-MADE LABORATORIES.

In spite of a vague theory held by the laity that a physician is a being apart and immune from all financial worries, the high cost of living is felt as keenly by him as by any other citizen. The thinning out of the ranks of the profession by the war, and the consequent withdrawal of numerous laboratory men into army hospitals will make it imperative for many a practitioner to dust off his books on uranalysis and blood examination and improvise a laboratory in his office. Then when he comes to the point of purchasing supplies for his laboratory he will find that they too have joined the aviation corps. There are many recent graduates who have been trained thoroughly in laboratory methods and would be glad to do all their own work as well as to help out some of their colleagues were it not that the beginning period of practice is too expensive anyway without indulging in high-priced laboratory equipment, and furthermore the best of these young men have been or will be called to the war.

How to acquire a satisfactory working laboratory with the minimum expenditure is told by M. J. Breuer, in an article published in the *Journal of Laboratory and Clinical Medicine* for March, 1917. The microscope is an unavoidable expense, and there are various small pieces of glassware which are indispensable and for which no satisfactory substitutes can be found. Instead of buying a costly centrifuge, however, Dr. Breuer suggests the purchase of a second-hand electric motor, suitable to attach to the usual electric lighting plugs, *i.e.* a 110-volt current; he himself found an electric fan motor very serviceable. He also goes on to describe how a satisfactory incubator can be made at home and a thermostat adapted from a "window flasher." A water-bath and shaking machine, constructed from inexpensive materials are also described in this ingenious article which should be read in the original.

Another clever idea is recorded in the April issue of the same journal. Dr. Simeon B. Kleiner, using the structural steel toy, which is found in so many homes just after Christmas, has constructed an apparatus for holding slides, while they are being stained at a cost of ten cents. As the writer suggests, other laboratory equipment may be easily devised by an inventive person and the great advantage is that any design found unsatisfactory can readily be taken apart and new ones constructed. We would suggest that inventive physicians purchase these toys complete and exchange the results of their experiments.

The above ideas are only a beginning. As we be-

gin to feel more and more the pinch of war, doubtless we shall revive the old American ingenuity which has lain dormant so long when our needs were supplied without effort, and then we may expect a host of other suggestions, equally clever.

OCULAR REACTIONS IN THE DIAGNOSIS OF DEATH.

The ether and dionine tests of death (absence of vascular reaction when dropped into the conjunctival sac) have been practised for some time because of their ready availability and simplicity. In this connection Terson (*Le Progrès Médical*, September 1) enumerates briefly all the alleged phenomena of death visible in the eye. Mere passive evidences are of no value, but induced reactions in the pupil and conjunctival membranes respectively are constantly in use. Passing by the agonal miosis followed by fixation as untrustworthy, he alludes to the action of atropine and eserine, which in certain cases might show by the activity of the iris that life is still present.

Of much more value is conjunctival irritation which may be practised in a great variety of ways on the cadaver. In the vast majority of cases there will be no vascular reaction two hours after apparent death even if the body is still warm. Ether instilled into the eye of a subject still alive would be unnecessarily severe, as in fact would ignipuncture, caustics, curettage, etc. On the other hand, the author uses dionine every day in the clinic, and while it induces an intense reaction, it is entirely inoffensive. Applied to the eye of a warm cadaver two hours after death, failure to provoke reaction should be legal proof of death. Either the powdered drug or the gycerole may be used for this purpose.

Acromegaly as Viewed by Marie's Predecessors.

Marie, who described and named this affection in 1886, never claimed that he was the first to behold it. In fact he found it described as early as 1772 and again in 1812 by distinguished clinicians of the day. He mentions no less than four Italians who had seen the disease before 1886 and this statement has influenced Ferrannini in *La Riforma Medica* for Sept. 1 to claim for his country the priority of rank. The four authors were all notable clinicians, especially Lombroso and Taruffi, the great authority on monstrosities. In 1864 Verga, one of the four, described acromegaly under the term prosopectasia, he evidently regarding it as limited to the face; but four years later Lombroso who termed a case a form of macrosomia or gigantism was clearly on the right track. In 1877 Taruffi demonstrated an acromegalic skull as a peculiar monstrosity, the actual report having been made by Brigidi, who saw in the "strange deformity" a manifestation of a chronic disease. The author would award the lion's share of the credit of discovery of the new disease to Verga and Brigidi jointly. There is not the slightest attempt to deprive Marie of full credit for making known to the profession this affection and for elaborating the clinical picture. One may add that an Italian, Massalongo, first recognized, in 1891, that acromegaly was connected with hypophysis disease; while even earlier (1886) Remiti had announced the discovery of the craniopharyngeal canal.

Pellagra and Polyneuritis.

Since the dissemination of the vitamine theory of the causation of deficiency diseases, cases have come to light here and there which appear to indicate the likelihood of the occasional coincidence of pellagra and beriberi or scorbutus in the same subject. Such associations are, of course, open to other explanations, especially as the secondary affection is more or less atypical. For example, polyneuritis in a pellagrin could be due to syphilis. In the *Brazil-Medico* for July 7, Dr. C. de Rezende reports an interesting case of polyneuritis secondary to probable pellagra. The doubt attending the diagnosis is based largely on the great infrequency of pellagra in the author's neighborhood. His patient was one of a number of subjects who could well have been pellagrins, judging from his description, yet he is unable to find any authentic records of the occurrence of this disease anywhere in Brazil. It is of interest, however, to note that an affection exceedingly like pellagra was described in Brazil in the seventeenth century, and it is probable that its non-existence in that country is apparent rather than actual. It is certain, however, that the disease does not occur in Brazil as a folk plague. The occurrence of an almost sporadic case of pellagra with secondary polyneuritis at once suggests that both conditions could depend upon the same insufficient regimen; or in other words, that the polyneuritic component might represent an atypical beriberi. But this is straining the evidence, because a sensory neuritis of a mild grade is very common in pellagra; and the author points out especially that the patient had no suggestion of beriberi, a disease with which he seems quite familiar. There was an absence of edema, circulatory disturbances, and other manifestations which attach to true beriberi. The polyneuritis in this case was mixed, sensory disturbances being more marked in the upper extremities and motor manifestations in the limbs, with resulting muscular atrophy.

Liviereto's Sign in Myocardial Insufficiency.

The so-called abdomino-cardiac reflex was first described in 1916 by Liviereto, and he has recently summed up the phenomenon in an Italian journal, abstracted in *La Presse Médicale* for August 16. Certain subjects had been found to complain of thoracic oppression, chiefly in the sternal area, after the act of eating. With oppression was often associated slight pain. Muscular effort, even light, was sufficient to cause the disappearance of the subjective symptoms. Such patients gave evidence of digestive or vascular disorders, although the heart was seemingly intact. Upon patients of this type mechanical irritation of the abdominal nerves causes an amplification of the area of the heart on percussion, which in turn subsides after moderate gymnastic exercise. Liviereto believes that this

dilatation of the right ventricle is due to vasoconstriction in the pulmonary arterial supply. Such dilatation cannot occur with a normal myocardium. The subjective sensations already mentioned indicate the presence of transitory dilatation. While the reviewer is silent on the point, it is evident that a certain amount of exercise can stimulate the weakened heart to the extent of overcoming the peripheral resistance. Our knowledge of this phenomenon is in its infancy, and it is to be hoped that research and observation along this line will increase our resources for cardiac diagnosis.

Effects of the War on German Synthetic Remedies.

Various synthetic drugs of German origin now official in the U. S. P. under their legitimate chemical designations are being sold under new proprietary names in France and Italy. It is stated that these substitutes are prepared after the original German formulæ. This is also the method pursued in the case of salvarsan and neosalvarsan substitutes. We also note a slight percentage of return to crude drugs, for example, in the case of valerian. Colloidal metallic and metalloid solutions are widely advertised and new ones are being introduced. The new burn remedies are also recommended for eczema and varicose ulcers. Preparations purporting to contain vitamines are made in Switzerland and in that country a substitute ichthyol is made. With a few possible exceptions in which Germany has had a virtual monopoly of raw material, it appears that their drug market monopoly, like the dye market, will be virtually forfeited after the war.

News of the Week.

The Draft and Physical Defects.—Statistics gathered as a result of the physical examination of drafted men, according to a statement issued by Dr. J. A. Nydegger of the United States Public Health Service, have shown an alarming number of instances of poor eyesight, under-weight, bad teeth, flat feet, and other defects. The figures bring out the fact that there are from seven to twenty per cent. more young men with defects or in need of medical attention in the rural than in urban communities. This is believed to be due to the fact that the health of school children is almost entirely neglected in country districts. A similar state of affairs was found to exist in England at the time of the Boer war, which they immediately set about correcting. We are said to be behind other countries in the physical training and care of the health of our school children.

A New Sing Sing Prison.—The old cell block at Sing Sing prison, which has long borne the name of the "death house," although not for prisoners condemned to death by the law, because of its insanitary condition, is to be demolished in accordance with a decision arrived at by the Commission on New Prisons. The work of demolishing the old prison will begin on May 1, 1918. Pending the erection of new quarters about eight hundred prisoners will be transferred to other institutions.

New York's Water Supply.—The celebration of the completion of the great Catskill aqueduct occurred October 12 and was marked by a number of public meetings and demonstrations by various organizations. The aqueduct is 120 miles long and is capable of delivering 500,000,000 gallons of water a day. Its construction has taken ten years. It has been completed within contract time, without a labor strike, and at a cost within the original estimate, $140,000,000. The celebration was taken advantage of to show the great influence of water supply on the public health. A pamphlet has been prepared by the Department of Health at the request of the Mayor's Catskill Aqueduct Committee for distribution to all the public school teachers throughout the city, with the suggestion that it be used as a text in the preparation of compositions on water supply. The pamphlet presents the main facts relating to the health aspects of the water supply.

Long Island College Hospital Medical School Inducts New President.—The inauguration of Dr. James Chidester Egbert into the office of President of the Long Island College Hospital Medical School were held in Polhemus Hall, Brooklyn, N. Y., on October 9. The induction address was made by Percy S. Dudley, President of the Board of Regents. After the address of acceptance by the President of the College, addresses of salutation and greeting were made by Dr. William Francis Campbell in behalf of the Council, Faculty and Alumni of the College and by Dr. Nicholas Murray Butler, Dr. Frank B. Blodgett and Dr. Samuel W. Lambert.

Rockefeller Foundation Aids Medical Education.—In cooperation with the General Education Board, the Rockefeller Foundation has turned its attention to the development of medical education in several of the centers of the country. In this field the Foundation and the Board of General Education have each contributed $1,000,000 for the development of medical education in connection with the University of Chicago. The Foundation is also cooperating with Johns Hopkins University in establishing a school of hygiene and public health. It has made an appropriation of $267,000 for this purpose. This new department opens this month, with Dr. William H. Welch as Director. Instruction and research facilities will be provided in hygiene, sanitation, and preventive medicine for physicians, biologists, medical students, chemists and engineers.

Rockefeller Foundation Reports on Hookworm, Malaria, and Yellow Fever.—The work of the Subsidiary National Health Board supported by the Rockefeller Foundation has been directed chiefly to the eradication of hookworm and in cooperation with the Government was extended to eight Southern States and fifteen foreign countries. The new fields of operation were Salvador, Brazil, Ceylon, and Siam, and early in 1917 work was started in the Fiji Islands, Papua, and Queensland, Australia. The Yellow Fever Commission, which consisted of Major General Gorgas, Dr. Juan Guiteras, Dr. Henry R. Carter, Major T. C. Lyster, Major Eugene R. Whitmore, and W. D. Wrightson, sailed from New York on June 14, 1916, and finished its work in South America in

December. The report of this Commission shows that so far as it could find the only endemic center of yellow fever in South America at present is Guayaquil, Ecuador. Certain South American countries call for close observation, and General Gorgas was appointed to direct the practical work along these lines. The war, however, has made it necessary to postpone most of the operation. An interesting experiment, covering a territory of 225 miles, is under way in Mississippi, which aims to demonstrate the practicability of the control of malaria through detecting the carriers and freeing them of malarial parasites.

New School for Nurses.—The Bellevue Hospital Training School for Nurses has decided to open a new department for the training of non-resident pupils as a result of the shortage of nurses occasioned by the war. There will be no tuition charge and textbooks and uniforms will be supplied to the applicants. The training will cover forty-eight hours a week. Applicants must have a high school or college education. This move has the endorsement of the official bodies related to war work.

Extermination of Mosquitos in Jamaica Bay.—The ditching of the Jamaica Bay marshes, which was begun last year, has been completed. Altogether five and one-quarter million feet of ditches were dug, at a cost of $88,625. Although the work had not progressed sufficiently to prevent all mosquito breeding this year, the results actually obtained augur well for the eradication of these pests in the near future.

Protest Against Building at Lake Mohansic.—The Joint Legislative Committee of New York State has been holding a series of hearings at the rooms of the Merchants' Association to decide what shall be done with the property acquired by the State for a hospital for the insane and a training school for boys at Yorktown on Lake Mohansic. Protests against having any public buildings whatever on this site were filed by Commissioner Williams of the Board of Water Supply, and representatives of the Department of Health, the New York Academy of Medicine, the Safety First Society, the Central Merchants' Association and a number of civic bodies. The committee has decided to visit the site and to hold another hearing on October 23rd.

Dr. M. Victor Safford, who has been attached to the Public Health Service of the United States Government and has been connected with the Immigration Service of the Port of Boston, has been engaged as deputy health commissioner of Boston.

Major B. W. Brown of the Public Health Service of the United States, now located at Camp Greene, has been elected assistant health officer of the city of Charlotte, N. C., at the request of the Government.

Examination for Assistant Resident Physician.—The Civil Service Commission of the State of New York announces a competitive examination for the position of first assistant resident physician for Iola Sanatorium for the Treatment of Tuberculosis, Monroe County. The salary is $1200 a year and maintenance. The position is open only to men who are citizens of the United States, graduates of an incorporated medical college, and licensed physicians of New York State. Applications must be at the office of the Commission at Albany by October 24, 1917.

Examination for Assistant Pathologist.—The Municipal Civil Service Commission of New York City is endeavoring to secure a number of competent physicians for the position of Assistant Pathologist. The position carries a salary of from $1,440 to $2,100 per annum. Candidates must be at least 21 years of age. Applications will be received at room 1400, Municipal Building, Manhattan, until Oct. 24 at 4 P.M.

Alvarenga Prize.—The College of Physicians of Philadelphia announces that the next award of the Alvarenga Prize, being the income for one year of the bequest of the late Señor Alvarenga, and amounting to about $250, will be made on July 14, 1918, provided that an essay deemed by the Committee of Award to be worthy of the prize shall have been offered. Essays intended for competition may be upon any subject in medicine, but cannot have been published. They must be typewritten, and if written in a language other than English should be accompanied by an English translation, and must be received by the Secretary of the College on or before May 1, 1918. Each essay must be sent without signature, but must be plainly marked with a motto and be accompanied by a sealed envelope having on its outside the motto of the paper and within the name and address of the author. It is a condition of competition that the successful essay or a copy of it shall remain in possession of the College; other essays will be returned upon application within three months after the award.

The Alvarenga Prize for 1917 has been awarded to Dr. Wilburt C. Davison, Baltimore, for his essay entitled "The Superiority of Inoculations with Mixed Triple Vaccine (B. typhosus, B. paratyphosus A. and B. paratyphosus B) over Successive Inoculations with the Single Vaccines, as Shown by Agglutinin Curves in Men and Rabbits."

Cornell University Medical College opened its twentieth session on October 1, 1917. The student assembly was addressed by Dr. William M. Polk, the Dean, who discussed the relation of the medical college to the present military situation and outlined the opportunities for patriotic service by students of medicine. The attention of the student assembly was called to the active participation in the work of the United States of America by the college, the members of the faculty, and the medical graduates by active service in the field and by providing facilities for the instruction of officers of the Medical Reserve Corps. The entering students were exhorted to continue their course that, in accord with the announced plan of the authorities, they may be prepared to fill the vacancies in the medical ranks which, with the continuance of the war, are certain to arise.

The enrollment is as follows: First year, registered in New York, 38 registered at Ithaca, 30; total, 68; second year, 54; third year, 29; fourth year, 27; graduates in medicine, 4; total 182. All students registered for the degree of M.D. (with the exception of those in the first year who are taking the seven-year course leading to the de-

grees of A.B. and M.D.) are graduates in arts or science. As a result practically all members of the first year class fall within the limits of the military draft. Several students, having been drafted into the National Army or fearing the draft in the immediate future, failed to register.

American Association of Obstetricians and Gynecologists.—At the thirtieth annual meeting of this association, held at Newark, N. J., September 17-19, 1917, the following officers were elected: *President*, Dr. Albert Goldspohn, Chicago; *First Vice-President*, Dr. Wm. Seaman Bainbridge, New York; *Second Vice-President*, Dr. Arthur T. Jones, Providence, R. I.; *Treasurer*, Dr. H. E. Hayd, Buffalo, N. Y.; *Secretary*, Dr. E. G. Zinke, Cincinanti, Ohio.

Addition to Seaview Hospital.—The cornerstone of the first of a group of cottages for the outdoor treatment of tuberculosis at the Seaview Hospital, New Dorp, Staten Island, was laid recently by Commissioner Kingsbury.

Plan Hospital Merger.—At a conference recently called by Felix M. Warburg, and attended by representatives of a number of the city hospitals, plans were considered for uniting the three large Jewish hospitals of the Bronx, the Lebanon, the Bronx and the Bronx Maternity. The plan considered calls for a new central hospital to cost at least $500,000, and providing accommodation for 300 patients. The plan also contemplates the establishment of dispensaries in different parts of the Bronx. A committee has been appointed of the representatives of the hospitals interested in this movement to make a survey and map out a plan for the merger.

Red Cross Aids China.—The American Red Cross has taken steps to render aid to the 400,000 persons made homeless by the flood at Tien-Tsin, China. The Red Cross has appointed Dr. Roger Green of the Rockefeller China Medical Board as the Red Cross representative in China. It is estimated that $200,000 will enable the Red Cross to render effective assistance in coping with this disaster.

Obituary Notes.—Dr. MELVIN SHELDON, a practicing physician of Brooklyn, N. Y., died at his summer home in Churchtown, N. Y., of pneumonia, on October 8, aged 51 years. He was a graduate of the Albany Medical College, in 1893, and assistant surgeon at the Good Samaritan Hospital.

Dr. HAROLD HAVELOCK KYNETT died at Philadelphia on October 1, at the age of 55 years. He was graduated from the Medical Department of the University of Pennsylvania in the class of 1886. He was for a number of years editor of the *Medical and Surgical Reporter*.

Dr. JAMES S. GILBERT, a practicing physician of Bordentown, N. J., died on October 11, aged 58 years. He was a graduate of the College of Physicians and Surgeons of Baltimore, in 1886, and has been Mayor of Bordentown for a number of years.

Dr. THOMAS JEFFERSON POWELL, a graduate of the University School of Medicine, Baltimore, in 1866, died suddenly at his home in Sylacauga, Ala., on September 30.

Dr. JOHN M. CROCKER, a graduate of Harvard University Medical School, in 1866, and for thirty years a practitioner of Cambridge, Mass., died of heart disease, on October 6, aged 72 years.

Dr. SILAS P. HOLBROOK, the oldest practicing physician of East Douglas, Mass., and the vicinity, a graduate of the University of Pennsylvania Medical School, in 1862, died suddenly on October 2, at the age of 80 years. He had made a professional call within an hour of the time of his death.

Dr. SARAH F. NORRIS, a retired physician, died in Hyde Park, Mass., on October 2. She practiced as medical missionary in Bombay, India, under the auspices of the Congregational Board of Foreign Missions.

Dr. FRANK H. GARDNER, a graduate of the Medical School of Maine, in 1878, died at his home in Morrill's Corner, Me., after a long illness, on October, 8, aged 63 years.

Dr. J. WESLEY STORK, a graduate of the Kentucky School of Medicine, in 1895, died of apoplexy at his home in Darmstadt, Ind., on October 1, aged 63 years.

Dr. JAMES H. ELLIOTT, a graduate of the University of Louisville, Ky., in 1909, died at his home in West Plains, Mo., on September 25, aged 46 years.

Dr. JOHN HENRY ALLISON, a graduate of Vanderbilt University, Nashville, in 1888, died at his home in Altoona, Ala., after long illness, on September 7, aged 55 years.

Dr. JOSEPH WEEKS, a retired physician of Topeka, Kan., died at the home of his son in that city, on September 26, aged 88 years.

OUR LONDON LETTER.

(From Our Regular Correspondent.)

THE WASSERMANN REACTION

LONDON, September 29, 1917.

THE London County Council has circulated a memorandum on the Wassermann reaction which was originally drafted by the pathologist of one of our hospitals for its venereal department. It has since been submitted to other pathologists who have made important suggestions which the council has embodied in a leaflet it is now circulating on the subject. This starts with the statement that the enormous number of tests which have been made during the ten years since the reaction was introduced have left no doubt as to the meaning to be attached to definitely positive or negative results in the great majority of cases, but in regard to certain points it cannot be said that universal agreement has been reached. The conclusions suggested in these special cases represent only the general trend of opinion. It is to be remembered that the Wassermann reaction is a quantitative one—*i.e.* it depends on a certain phenomenon occurring in a certain degree; hence there will always be border-line reactions, which, while showing a distinct departure from the normal, are not sufficiently marked to serve as a basis for a definite diagnosis, except under special circumstances. When such reactions occur they must be carefully considered in relation to all the known facts of the case in question. A well-marked positive reaction, obtained with the full technique, or with a modification involving only unessential

details, justifies a definite diagnosis of syphilitic infection, provided that we can exclude leprosy, yaws, and perhaps sleeping sickness, and these seldom call for consideration in this country. A positive Wassermann reaction sometimes is obtained in malarial cases, where there is a complete absence of symptoms of syphilis, and no suggestion—in history or otherwise—of a previous taint, and this point must be considered in some cases.

The reaction is first met with between the second and sixth week after the appearance of the primary sore. Up to the latter date an indefinite result is obtained in a certain proportion of cases, and during the first three weeks, much more certain information may be obtained by examining the chancre for the presence of the *Spirochæta pallida*. If this examination gives a negative result, and the case is clinically suspicious, a Wassermann reaction should be carried out, and if negative or indefinite, repeated in about a week. A single negative result obtained during this period is of no value in excluding syphilis.

From the sixth week onward, and throughout the whole period of secondary manifestations, practically every case gives a well-marked positive result, provided no treatment has been begun. Therefore, if a patient presents lesions, which if syphilitic, would be in the secondary stage, and yet responds negatively to the test, great care is to be taken before diagnosing syphilis, and it would be well in such a case to submit it to an expert. Later stages, with some exceptions (as aneurysm and general paralysis) do not show quite so high a proportion of positive results, but the great majority of cases, *e.g.* those showing ulceration of throat and tongue, etc., give a definitely positive reaction. Thus, although a negative result has not the practically conclusive import which it possesses in the secondary stage, yet it should weigh strongly against a diagnosis of syphilis, especially if it can be ascertained that the patient has never undergone any antisyphilitic treatment.

OUR LETTER FROM PARIS.

(From Our Regular Correspondent.)

RED CROSS ORGANIZING—THE REORGANIZED AMERICAN HOSPITAL—HANDLING OF THE WOUNDED—ANESTHESIA FOR MINOR OPERATIONS.

PARIS, September 10, 1917.

THE dissatisfaction and mild opposition encountered by the American Red Cross upon its arrival in Paris under the direction of Major G. M. P. Murphy, Commissioner for Europe, is disappearing as the real aim and scope of the work proposed are understood and its evident benefits appreciated. By the coming of the United States into the war, a changed condition was created for all American Relief Societies and activities, and the coming of the United States army has made that change effective.

The work done during the first three years of the war by those Americans, both in France and America, who gave their money, time, and strength to relieve the suffering among the Allies, should be publicly acknowledged as a great example of self-sacrifice and generosity, and to the people who carried on this work the thanks of all American citizens are due. No new organization coming into the field now has any right to take action that will in any way diminish the credit which is due to the existing societies and organizations or which will in any way lessen the effectiveness of their work; rather it should be the aim of all newcomers into this field to strengthen in every way possible the existing organizations and to increase their power for doing good.

It must be recognized, however, that certain difficulties have arisen which it will require new machinery to meet, and only by the pooling of interests can this result be accomplished. The difficulty of effectively distributing relief increases month by month as the war goes on. The great problem which confronts all American effort in France is the problem of transportation—both ocean and inland. Even before the entrance of the United States into the war, the tonnage available was not sufficient to meet the situation adequately, and the strain put upon that transportation has been enormously increased by the coming of the United States Army to France. This, in fact, is the great central factor which compels new measures, and the controlling element in these measures is the United States Army. The army will apportion the available tonnage and railroad transportation as it deems wise, and in view of the fact that it is obviously impossible for the army administration to undertake to deal with a great number of individual relief organizations, it has chosen, and the people of the United States have been requested to consider the American Red Cross as the central organization through which relief work should be carried on by Americans in this war. The army also recognizes the essential value of the Y. M. C. A. and will confine its dealings with the relief and social problems largely to these two organizations. The Red Cross, in fact, is in a sense associated with and under the control of the army and may properly be termed a governmental organization; therefore, it has seemed wise that the Red Cross should not attempt to use the limited transportation facilities at its command for the distribution to points which are determined in America of a very large number of individual contributions, but that it should receive contributions from all these individuals and societies in America that are willing to trust these contributions to its care, and that it should distribute them in such places as seem best to it and its associated societies in France, and to such places as the distribution facilities at its command make possible.

The Red Cross announces that it in no way wishes to limit or interfere with the space and facilities which others are able to procure; that it only wishes to use those facilities which it is able to obtain in a way which its officers believe will best enable the society to carry out the duties with which it has been entrusted and which will best fit in with the needs of our army, and will best carry out the desire which all have in their hearts to do the greatest good in the best way. In order to do these things, they believe that the best way is: (1) That the Red Cross here, aided by the experienced relief societies, should classify, standardize, and requisition in the order of their importance the relief supplies which are needed here and should determine what may either be purchased on this side or dis-

pensed with altogether in order to save transportation space and at the same time fill the most pressing wants. (2) That the Red Cross at home, aided by the experienced societies and relief organizations in America, should provide in a systematic way for furnishing the relief supplies so indicated as needed here and which may not be purchased here, and for their shipment in the order of their urgency.

The women's hospital committee of the American Red Cross Military Hospital, which has been organized by Mrs. Alfred E. Bradley, wife of Colonel Bradley of General Pershing's staff, held its first meeting at the hospital in Neuilly yesterday afternoon. The hospital committee is practically the reorganization of the former woman's auxiliary committee of the American Ambulance, its duties being along the same lines, with the exception of the raising of funds, and its members being practically the same. The full list of members of the former woman's committee have been invited to continue their work under the new military administration of the Ambulance, and Mrs. Bradley announced yesterday that two new members, Mrs. Sandford H. Wadhams and Mrs. W. K. Vanderbilt, had been added to the list.

They have already commenced their work in cooperation with Colonel Peed, who is the military administrator of the hospital, to improve the ambulance by arranging special wards for the officers. Three wards on the second floor are being entirely renovated and beautifully installed for officers' wards. Flower boxes have been placed at the windows, which alone give the rooms a cheerful aspect, and the woodwork and beds have been repainted and the rooms made to look cosy and homelike and less like hospital wards. An officers' lounging-room is also being installed, where the officers who are able to be about may have a place to receive their guests and a room for reading and writing.

Many other improvements have been made recently under the military administration, which not only add to the comfort of the patients, but which have proved a great saving in work for the staff. A new feeding system has been inaugurated. The patients who are able to be out of bed are permitted to go to the dining-rooms, while those who are confined to their beds are fed from carts which carry a basin of coals under sliding drawers containing the food, thus keeping it piping hot. These carts are wheeled from ward to ward and are proving of excellent service as time-savers. Two auxiliaries have served seventeen wards in seventeen minutes.

It took fully a year to organize the proper handling of the wounded, after the commencement of the war, and during that time nearly all the wounded arriving in Paris and other interior points, were in generally bad condition. It is with great satisfaction that we see today the errors and false ideas of the early months dissipated and corrected. The wounded arriving since the Verdun offensive are all in the best possible condition. They have all been excellently operated upon, or their wounds thoroughly cleansed, renovated, and perfectly bandaged, and arrive in Paris from the point of evacuation in a single day's journey.

This new state of affairs is extremely fortunate for the Paris hospitals, for the reason that, as the war continues, they have steadily lost their personnel, until now it is becoming a grave question how to conduct the service properly and the question is being agitated of calling back from the front some of the younger men who have performed three years' service there, to take charge of some of the hospital services that are at present without heads. At the present time the Department of Public Assistance is embarrassed to find heads for vacant services in the Municipal, Boucicaut, Bichat, and Lariboisière Hospitals. This question is equally engaging the attention of other large cities, all of which are centers for the care of the wounded, and where there is a serious lack of sufficient medical men to do the work.

In Italy they have solved this question with a fair degree of satisfaction, by returning surgeons to Rome, Florence and Milan during the quiet periods between attacks, when they take up their service in their home hospital and return to the front when called by the imminence of another offensive.

Dr. Legueu, at Cochin Hospital, showed me a pretty trick in local anesthesia for minor operations, as opening an abscess, passing a sound, cutting an adhesion, or any simple thing occupying not more than five minutes. It consists in soaking a pledget of cotton for each nostril with pure chloride of ethyl and causing the patient to close the mouth and breathe deeply through the nose; almost instantly all sensation is dulled. I saw him slit up and free a difficult phimosis under its influence.

4. Feeble-Mindedness as an Element in Poverty.—Robert W. Kelso defines the word poverty as the more or less chronic insufficiency of the means of keeping a reasonably sanitary abode and enough food and clothing to maintain the body in good working condition—plus the additional means of like maintenance for those properly dependent. Back of the superficial causes, which are given, whether it be in the immediate generation or in the next or the next, there will be discovered a fatal lack of judgment, a defect of will, a mental dulness that has brought this train of troubles to its progeny. He further states that no consideration other than this close relationship between feeble-mindedness and poverty could with equal force bring out the true significance of that dreadful fact about feeble-mindedness,—namely, that it is hereditary in at least 80 per cent. of the cases. The practical definition of a feeble-minded person is one who, though capable of providing his living with his hands, is unable, by reason of mental defect, to make his living in competition with his more intelligent fellows. When we realize that the feeble-minded citizen is by definition a pauper, and when we further consider that the condition breeds as true as the spots on a dog, we can vaguely picture to ourselves the tremendous social saving in preventing their propagation, and the incal-

culable social waste attending our neglect to catch this social opportunity at the flood tide.

2. Etiology and Treatment of Frequency of Urination in Women.—William E. Stevens gives somewhat over fifty causes for frequency of urination in women. He states that as frequency of urination is a symptom rather than a disease, successful treatment is necessarily dependent upon the discovery and removal of the primary etiological factor as well as the secondary pathological conditions. It would be manifestly absurd, for instance, to attempt the cure of an ulcerative tuberculous cystitis while the primary focus in the kidney remained untouched. Brief mention will be made of the treatment of a few of the more common conditions responsible for the above symptom. *Trigonitis and urethritis associated with pyelonephritis.*—The keynote in the treatment of pyelonephritis, as in infections elsewhere in the body, is drainage. This is accomplished by means of the ureter catheter, which at times should be permitted to remain in position for a period of from several hours to two days. The solution used for pelvic lavage and the strength of the same is of minor importance if the pelvis is thoroughly emptied before its introduction. Bimanual pressure upon the kidneys assists in accomplishing this result. Another factor of importance in the treatment of pyelonephritis is the determination of the range of acid production or hydrogen ion concentration exhibited by the various groups of colon bacilli, to infection with which pyelonephritis is usually due. We may thus ascertain in which direction the reaction of the urine must be adjusted and whether alkali producing drugs, as potassium citrate, or those rendering the urine acid, as sodium benzoate and acid sodium phosphate, are indicated in order to bring about conditions unfavorable to the growth of the organism. The paracolon bacillus, while less common, is of greater virulence than the colon bacillus and is frequently found in alkaline urine. Trigonitis, as a rule, disappears quickly under the use of bladder irrigations and topical applications of silver nitrate, while good results are also obtained in the treatment of urethritis with 2 to 10 per cent. solutions of the same drug. Previous massage of the urethra, often over a sound, is helpful. *Prolapse of the posterior urethral wall* is best treated by operative measures, a portion of the superior vaginal wall, beneath the urethra, being resected and the fascia brought together, following the technique used in operating for cystocele. Prolapse of the uterus, if present, should also be corrected. Gradual distention of the bladder with normal salt or boric acid solutions and the occasional passage of sounds have often resulted in improvement in those cases where no apparent cause for frequency has been detected.

10. Operative Treatment of Tuberculosis of the Knee Joint in Adults. Robert B. Osgood and Edward C. Bull.

10. Operative Treatment of Tuberculosis of the Knee Joint in Adults.—Robert S. Osgood and Edward C. Bull state that tuberculosis of the knee joint in adults differs in two important points from the same disease in children: (1) In children there are centers of growth in direct anatomic relation to the joint. Disturbance of these centers by the disease or by operative interference may seriously affect the ultimate length of the limb. This condition requires consideration and treatment. (2) In children there seems to be a more marked resistance to the disease than in adults, and cures with only slight disturbances of function often occur when persistent, and continuous local fixation is combined with general treatment by heliotherapy and an antituberculous regimen. In adults the disease, when once established, may be said, according to their experience, never to fully recover without operative interference of some form. It is their belief that an operation should be contemplated as soon as the diagnosis has been made. They further state that it is often wise to defer the operation in a case in which there has been no fixation and in which the knee is in a more or less acute and irritable state. Such a patient should be put at once at complete rest and freedom from weight-bearing for perhaps a month, and when the acuteness of the disease has subsided, the appropriate operative procedure may be more safely executed, with less postoperative reaction. Only two types of operation have for many years been considered in the clinic: the one conservative of function and representing little or no shock, attempting to cure the disease by keeping synovial surfaces apart and bathing them in an antiseptic oil; the other destructive of function, a major operation, attempting to cure the disease by destroying the joint and eliminating the synovial membrane and the red bone marrow. When they believe that the tuberculous disease exists only in the synovia, they have been advising their adult patients to submit to an exploratory arthrotomy through a 3-inch lateral incision, and if no bony disease can be found at operation and the macroscopic findings are consistent with tuberculosis, they have been injecting a bland olive oil containing 4 per cent. of iodoform after the method of Brackett. Suffice it to say that from 1 to 5 ounces of the 4 per cent. iodoform oil are injected after the joint has been opened, the fluid evacuated, and the adhesions and pannus, if it exists, carefully separated. The deeper layers of the capsule and the synovia are closed by a continuous stitch from each end, a small opening being left in the middle for the nozzle of the glass syringe. A special double loop lock stitch is inserted and pulled tight about the nozzle, and the oil injected with considerable tension and the lock loop pulled home. Oil has been recovered from the joint eight weeks after the operation in an apparently unchanged condition. Complete fixation is never employed, though the patient bears weight in a split cast only after several months. They conclude as the result of their treatment for this condition in the Massachusetts General Hospital since 1907 that: (1) Tuberculosis of the knee in adults is not fully cured without operative treatment. (2) Primary synovial tuberculosis of the knee in adults exists and is frequently improved or cured by inflation of the joint with iodoform oil. (3) We have seen no permanently satisfactory function restored in cases with bone involvement. (4) Excision of the knee is the method of choice in cases with bone involvement. (5) The position of choice is from 15 to 20 degrees' flexion for ambulatory vocations, and from 35 to 40 degrees' flexion for sedentary occupations. (6) Bone plates, where the bone is firm, and the kangaroo tendon "bundle tie," for conditions in which there is much atrophy, are valuable means of internal fixation. (7) Function is important for final bony union after excision.

7. The Effect of *x*-Rays Upon Diseases of Bacterial Origin. Christopher Kempster.
8. The Biological Aspects of Warfare. Harry Campbell.

7. The Effect of X-Rays upon Diseases of Bacterial Origin.—Christopher Kempster states that during recent years there has been an increasing application of the *x*-rays as a means of treatment of diseases of bacterial origin, both superficial and deep-seated, with results which have in many cases been surprisingly successful; cases which under other methods of treatment either became worse or had not improved at all making a rapid recovery. This has led to an inquiry as to whether the *x*-rays possessed any specific germicidal action. A diversity of opinion has arisen on this point. Upon the principle that there is no result without a cause, there must be some good reason why evidence so contradictory can be produced. The one set of investigators have based their claims upon findings made as the result of experiments and observations of the action of *x*-rays upon microorganisms in living animal tissues—a distinction of the utmost importance and one which will reconcile these opposite opinions and prove them both to be true. He shows that the action of *x*-rays upon bacteria in inert media is not germicidal, and also that the absence of bacteria in living animal tissues after irradiation is not due to the lethal action of the *x*-rays but to the stimulation of the living animal tissues, leading to increased phagocytosis and so to the disappearance of the microorganisms, and that the phagocytosis is materially aided by the action of the *x*-rays upon the bacteria. Experiments were thoroughly conducted for proof, and Kempster presents his conclusions as follows: It might well be said that if the increased phagocytosis is due to increased stimulation of the tissues, what proof is there that the *x*-rays play any part different from that of any other stimulant applied to the region? The answer is that if tuberculous glands, such as are commonly met with in the cervical region, be subjected to the influence of the *x*-rays, they will in course of time atrophy and become sterile of tubercle bacilli, whereas glands of a similar nature exposed to stimulation of other kinds, such as fomentations, poultices, iodine, etc., do not atrophy and become sterile, but rather increase in size and bacillary virulence. We thus see that the phagocytosis, encouraged by the applied stimulation, is not alone sufficient to prevent infection; it follows, therefore, that the *x*-rays must play an important and specific part in the prevention of the infection by and in the destruction of the bacilli. We found that when the tubercle bacilli were exposed to the rays they did not form colonies, and we also found that developed colonies exposed to the rays did not grow, that the bacilli were not destroyed in either instance, but that their increase and multiplication had been inhibited. This, then, is the reason why inoculated guinea-pigs when subjected to the influence of the *x*-rays do not develop tuberculous lesions. The phagocytes are equal to the task of destroying the germs inoculated into the animal if the germs are deprived of their power of rapid reproduction, but if their reproductivity is not inhibited the phagocytes are unequal to the task of dealing with the ever-increasing invading forces. We may therefore conclude that the effect of *x*-rays upon diseases of bacterial origin is that they have not any germicidal powers, but that they have a decided inhibitory effect upon the reproduction and increase of the germs, and that they produce stimulation of the living tissues leading to an increased phagocytosis, which is capable of destroying an unreproductive colony of microorganisms.

Le Progrès Médical.

August 25, 1917.

Voltaic Vertigo in Affections of the Internal Ear.—Bourgeois discusess the so-called Babinski test in which the two poles of a galvanic circuit are applied respectively over each ear. In the normal subject when the current is made the head is inclined toward the trunk on the side of the positive pole. This is the so-called voltaic vertigo test as described in standard works. Babinski in making this test has the subject walk with closed eyes, this modification necessitating long conduction wires. With a mild current the subject tends to deviate slightly to one side in his walk. If the labyrinth is normal patient inclines the head when an intensity is reached of 6 milliamperes. He feels slight vertigo and an irresistible impulse toward the side of the positive pole. A stronger current produces nystagmus, but by this time the patient is unable to tolerate it. If there is hyperexcitability of the labyrinth a weaker current—1 or 2 milliamperes—is sufficient to induce Babinski's sign. Even then the effects of the current may be severe, vertigo being pronounced. In hypoexcitability conditions are reversed for as high as 15 milliamperes may be required to induce the least degree of vertigo. But in severe involvement of the labyrinth and irrespective of the direction of the current patient tends to fall towards the affected ear; and if both ears are involved, toward the worst ear. The author has made free use of these tests and is able to corroborate the laws as enunciated by Babinski. The latter published his discoveries before Barany had introduced induced nystagmus into diagnosis. It has been disputed that the Babinski test controls only the labyrinth. It is true that in addition to labyrinthic symptoms the patient experiences a salt taste and hears a sonorous sensation, but these phenomena are localized. There is no evidence of central excitation. The passage of the current through the petrous bone causes only peripheral phenomena. It is held often that the Barany test is sufficient, but the Babinski reveals the degree of excitability of the semicircular canals; by its use we can in a few minutes ascertain the functional state of the vestibule. The author would begin the examination with the Babinski, just as he would also determine the state of hearing by the Lombard test. He has used the former with great success in a series of 12 cases. Four patients had normal vestibular apparatus as determined by the amperage required to produce head inclination. One who withstood 18 milliamperes had total unilateral labyrinthine deafness, due to a projectile wound. Four with shell shock showed hyperexcitability of the labyrinth. In three there was no inclination toward the positive pole, but the tendency to fall toward the affected side. The same phenomenon was seen in a patient with Ménière's disease.

La Presse Médicale.

August 23, 1917.

Treatment of Typhoid Osteoperiostitis by Vaccinotherapy and Surgical Intervention.—Weil and Chevrier have treated 12 patients in this manner, in 10 of whom the lesions were located in the ribs. During the present war from 80 to 90 per cent. of these bone complications of typhoid have been seated in these structures. There must be some good reason for this unusual incidence, but it cannot be traced to any external factor and the authors can only suggest excessive function of the ribs incidental to the age of the soldiers and exertions of warfare. The bone lesions represented sequelæ and every patient treated had undergone a severe, protracted type of fever. The majority had not been vaccinated and every case was true typhoid. A blood find is not enough to decide as to the pathogenic organism, which must be found present in the lesion itself. This need not of course be determined in advance of operation for it is assumed that some cases will already be in the fistulous stage while others will demand prompt intervention. Agglutination was positive in 11 of the 12 patients, 7 of them at 1-500. The management begins with vaccinotherapy in all cases, which have not suppurated with the expectation that operation may not become necessary. There were but two such cases and both recovered without other treatment. The same measure is used in suppurative cases, whether closed or fistulous, but without much anticipation of a permanent cure by this means alone. Such a fortunate outcome can, however, occur. Apparent recovery was

obtained in five cases, but sooner or later signs of local infection reappeared both in the closed and fistulous cases, so that some form of intervention, usually radical, became necessary. Despite this liability to recur, the authors would always begin treatment with vaccination because of the possibility of a cure without operation and of cure with slight intervention. In the most favorable case the focus of suppuration was almost suppressed. The scar opened and a single drop only of pus appeared. Operation was not required. It therefore appears that in 3 patients at least vaccinotherapy could be regarded as curative. In regard to the others vaccination certainly prevented the development of sudden destructive suppuration.

Jacquet's Disease.—Sabouraud discusses the association of baldness with dental anomalies originally agitated by the late Dr. L. Jacquet under the designation of reflex alopecia. The author at the time opposed this view. The nails, hair, and teeth have affinities of origin so that developmental or involutional deficiencies should be found to occur side by side in the three systems. This association might be in part latent. Hereditary syphilis suggests itself as affording an opportunity to show the presence or absence of a common dystrophic factor. The author discusses the dental stigmata of this affection. Dental teratology need not of course be synonymous with heredosyphilitic teeth. On the contrary, while there are numerous recognized types of imperfect or monstrous dentition which appear incidentally here and there in the children of syphilitics many of them are not specific. The author has numerous models of the teeth of bald subjects in which the four basic forms of dental dystrophy are present. He finds enough evidence to uphold the dictum that these dystrophies accompany both severe and mild forms of alopecia, and that in addition to scalp baldness the other hairs of the body and the nails may participate. Baldness is in part latent because after loss of hair the latter may grow in again. The subject should be investigated systematically, including the employment of serological tests, Sabouraud says, in order to determine whether or no Jacquet's syndrome is of syphilitic origin.

August 4, 1917.

The Tuberculosis Problem in Rio de Janeiro—Barbosa in the course of a serial article on this subject mentions that at least 90 per cent. of the tuberculosis in the Brazilian metropolis is of transmissible types, man to man. The vehicle of transmission is the sputum, and cultures of bacilli are not obtainable save from animal tissues and discharges. Whether a house can become "infected" in the figurative sense is more than doubtful. Such a house could hardly exist in the absence of a subject with active tuberculosis. Bacilli cannot multiply or even survive long in dried sputum and dust. Every case of tuberculosis should be discovered and notified, naturally without the employment of force. The Inspector for Tuberculosis should then decide as to whether or not the case is an open or contagious one in the latter event whether it is best suited for home or hospital control. In the home case the patient chooses his own physician while the Health Department looks after the hygienic and sanitary end. The closed case must also be controlled, if there is a possibility that it could become an open one. These patients require simply hygienic control. In Rio there are needed 75 inspectors and even a thousand subordinates, to control the very large contingent of tuberculous subjects in a satisfactory manner. At present hospital facilities for isolation and treatment are insufficient. While new pavillions are being constructed the use of camps in the woods is suggested.

The Enterokinetic Action of Pituitrin.—Pimentel refers to a pioneer report on this subject by Haussay and Beruti in 1915. This use of the remedy has been tested in Cuba and the principal question is in reference to a possible superiority over orthodox purgatives. That pituitrin should be able to stimulate intestinal peristalsis is a foregone conclusion, but earlier studies limited themselves to statements that such an action while present was only transitory. The author relates a number of cases which tend to show that a hypodermic injection of 1 c.c. will often empty the bowels in 5 or 10 minutes. One patient passed 3300 grams of fecal matter in 5 minutes. In other cases, however, in which the remedy was employed, the result was slow or negative and there was nothing apparently gained by the use of the pituitary extract in this way.

Hygiea.

July 16, 1917.

Series of 221 Myoma Laparotomies.—Lindqvist after a brief history of the development of the radical abdominal myomectomy reports a tabulation of 221 operations with reference both to immediate and end results. In 65 cases total hysterectomy was done while in 121 cases supravaginal myomectomy was the intervention. The other patients were submitted to conservative operations. The author lost but two patients, each from pulmonary embolism (no mortality after conservative methods). Among post-operative complications were 16 examples of thrombosis, while next in order numerically were 14 cases of vesical disturbance, the ureters escaping injury. End results were as follows: of the panhysterectomy cases 94.2 per cent. ended satisfactorily. The corresponding per cent. for the supravaginal operation was 81.1. Despite this apparent superiority the author has become a partisan of the more conservative of the two interventions and will employ it in selected cases. The amount of disturbance caused by the artificial climacteric was large, for more or less of it was present in 45 per cent. of cases. If one ovary had been left behind, Lindqvist believes, these disturbances could have been very markedly reduced in amount.

Journal de Médecine de Bordeaux.

August, 1917.

Traumatic Periosteoma.—Rocher reports nine cases of this sequela of traumatism, the latter usually due to the tangential impact of a projectile. The pathology is simple, for the inflamed periosteum makes new bone in the zone of contusion. In peace times the shin is the most likely seat of this lesion, youthfulness furnishing a predisposition; but in the author's war material the trochanters were involved in 5 of the 9 cases. In peace surgery infection is not common, but in warfare the reverse seems to be the case. At least, but 4 of the 9 cases were aseptic, and suppuration with or without fistulation is therefore the menace in a large number of cases. This course is due to several factors. The projectile may have been lodged in the wound area, and it may or may not have caused necrosis of a splinter of bone. The abscess cavity or fistula in such a case would then show a tendency to develop fungosities. The general configuration of the periosteoma shows marked variation. In case I it was spur shaped and hence much in the way, in addition to causing painful irradiations. It was easily ablated with the scissors. In the second case the periosteoma exhibited a tendency to "mushroom." In the more deeply seated lesions an *x*-ray was necessary to map out the contour and in such cases nerve filaments could readily be involved in the contusion area. A dissection operation then became necessary, with removal of osseous tissue by morcellation. In fistula cases bismuth paste was used in radiodiagnosis. To reproduce a case in some detail, patient No. V was struck over the right subtrochanteric region by a shell fragment. The entire wound region corresponded to the external surface of the upper third of the femur, and the foreign body remained in this area, from which it was extracted the following day. A free suppuration of the wound was followed by tetanus, which ended in recovery. The *x*-ray showed an osteoma as large as a hen's egg in the subtrochanteric region. The trajectory of the projectile persisted as a fistula, suppuration from which could not be arrested. For this reason and because the tumor was a mechanical nuisance the latter was removed by morcellation. The osteoma was found to be the seat of a fungating osteitis. A satisfactory recovery followed the operation.

Book Reviews.

THE MEDICAL CLINICS OF NORTH AMERICA. Vol. I, No. 1, July, 1917, Johns Hopkins Number. Price per year, $10.00. Published bi-monthly. Philadelphia and London: W. B. Saunders Company.

THIS publication is intended to supersede the Medical Clinics of Chicago, and is meant to be representative of what is best in this line in the entire country. Through such a medium, men who are not able to visit regularly the large teaching hospitals can keep in touch with what is new in diagnosis and treatment. This first number contains much of interest from the clinics of Doctors Janeway, Barker, Mosenthal, Futcher, Hamman and Brown of the Johns Hopkins Hospital. The teaching is based on patients brought into the clinical amphitheater for demonstration before the students. Seriatim the cases presented are as follows: Hodgkin's disease with extensive skin eruption; postural albuminuria; diabetes associated with disturbances of the external secretion of the pancreas in a syphilitic; meningitis of unknown etiology probably meningococcal; fibrillation of muscular tissue; essential hypertension; dietetic treatment of diabetes mellitus; acromegaly; combined scleroderma, Raynaud's disease and chronic arthritis; hypertension, its clinical aspects; dermoid cyst of mediastinum; Milroy's disease; some gastrointestinal notes; visceroptosis and chronic appendicitis; the medical after-care of surgical patients after abdominal operations.

The number is replete with practical points and is characteristic of the thoroughness in clinical teaching for which Johns Hopkins Hospital is noted.

THE MODERN MILK PROBLEM IN SANITATION, ECONOMICS, AND AGRICULTURE. By J. SCOTT MACNUTT, Lecturer on Public Health Service in the Massachusetts Health Service in the Massachusetts Institute of Technology; Author of "A Manual for Health Officers." Price, $2.00. New York: The Macmillan Company, 1917.

ANYBODY who has given thought to this subject will readily concede that there is a "milk problem" and that it is becoming more important every day, especially in New York. The reason for such a state of affairs is lucidly explained by the author in this small book, and after perusing the pages one unavoidably gets the impression that the "problem" takes the form of a vicious circle in which the farmer, the dealer, and the consumer are engaged in a fruitless controversy, each accusing the other of being in the wrong. The fact of the matter is, as the author points out, that the economic factors involved at the present time are so complex as to preclude any permanent settlement, unless all parties concerned are willing to meet one another half way. The author explains how this might be accomplished, and considers the subject from every angle. We can recommend this book as being a thoroughly sound exposition of a most perplexing problem.

COLLECTED PAPERS OF THE MAYO CLINIC, ROCHESTER, MINNESOTA. Edited by Mrs. M. H. MELLISH. Volume VIII, 1916. Octavo of 1,014 pages, with 411 illustrations. Price, cloth, $6.50 net; half morocco, $8.50 net. Philadelphia and London: W. B. Saunders Company, 1917.

THE further extension of endeavor in the field of scientific research made possible by the Mayo Foundation for Medical Education and Research in the Graduate School of the University of Minnesota has resulted in such a plethora of material contributed by those connected with the Mayo Clinic proper and the Mayo Foundation that it has been found necessary this year to still further limit the percentage of published papers that could be reprinted in full in this annual. Consequently, not only have certain papers been abstracted for this volume, but a few of the articles read or published in 1916 by the staff of the Mayo Clinic have been omitted entirely and a number of others have been held over and will be included later in more comprehensive studies on the same subjects.

There are forty-two contributors to the present volume. The arrangement of material is the same as has obtained previously except that since, during the past year, so much more work has been done on the blood, this subject is for the first time accorded a separate heading. The headings and number of articles in each division as are follows: Alimentary Canal, 29; Urogenital Organs, 14; Ductless Glands, 14; Blood, 7; Head, Trunk, and Extremities, 12; Technique, 6; General, 11. Many of these articles present the most advanced work that has been done in the respective fields; and the fruits of the correlation of labor of the clinician, operator, and pathologist perhaps reach their best exemplification in certain of the articles reprinted in this volume.

As we have repeatedly indicated in previous reviews, these volumes are of exceptional value to the progressive surgeon, and the current volume with its varied contents seems in many ways the most important that has yet appeared.

CORNELL UNIVERSITY MEDICAL BULLETIN. Vol. VI, No. 4, April, 1917. Studies from the Department of Surgery, Including Urology, Gynecology, Laryngology, and Ophthalmology. Published by Cornell University, New York City.

THIS consists of a collection of reprints of twenty-six articles written by various surgeons connected with the departments of surgery, urology, gynecology, and ophthalmology of Cornell University. There are fourteen articles from the department of surgery, six from urology, one from gynecology, three from laryngology, and two from ophthalmology. One of the articles from the department of ophthalmology and all three from that of laryngology were originally published in medical journals during the year 1914; all others in 1916 or 1917. Most of these articles are well worth keeping on file, and their collective publication by the authorities of Cornell University not only renders this easy but also serves to call attention to some of the excellent work that has been done during the past year by members of the teaching staff.

EXPERIMENTAL PHARMACOLOGY. By DENNIS E. JACKSON, Ph.D., M.D., Associate Professor of Pharmacology, Washington University Medical School, St. Louis. With 390 original illustrations, including 24 full-page color plates. St. Louis: C. V. Mosby Company, 1917.

AS the title denotes, this is purely a laboratory book. We know of but two earlier works in English of the same scope, to wit, Hermann's, published in 1883, and Greene's, the last edition of which appeared in 1909. Both of these are small efforts—in fact, Greene's contains but 76 pages. The present volume of 526 pages practically has the entire field to itself, and its only competitor for world honors is the third edition of the German work of Meyer and Gottlieb (1914), which is devoted to both clinical and experimental pharmacology, but which is not in any sense a laboratory guide and is relatively poor in illustrations. Hence Dr. Jackson's exhaustive work, standing alone, is practically beyond criticism at present. Time alone will proclaim its actual value. Dr. Halsey's translation into English of the original edition of Meyer and Gottlieb's book should make an excellent companion for Jackson's laboratory guide, for the two works exhaust the possibilities of experimental pharmacology.

POTTER'S COMPEND OF MATERIA MEDICA, THERAPEUTICS AND PRESCRIPTION WRITING. With especial reference to the Physiological Action of Drugs. Based on the ninth revision of the U. S. Pharmacopœia; including also many unofficial remedies. By A. D. BUSH, B.S., M.D., Professor of Physiology and Pharmacology, Medical Department, University of Southern California. Eighth edition, revised. Price, $1.25 net. Philadelphia: P. Blakiston's Son & Co.

THIS book, which is intended chiefly for medical students, contains the essentials of materia medica. The alterations that have been made in it are such as will bring it into conformity with the recently issued U. S. P. This latter publication lists preparations that will not be found in the compend, and the compend is swamped with numberless unofficial preparations which the student will do well to ignore. The book is marred by numerous misprints, and when dealing with the few Greek words in the early part of the volume, the printer seems to have taken full advantage of his opportunities for mischief.

HANDBOOK OF ANATOMY. Being a Complete Compend of Anatomy, Including the Anatomy of the Viscera, a Chapter on Dental Anatomy, Numerous Tables, and Incorporating the Newer Nomenclature Adopted by the German Anatomical Society, Generally Designated the Basle Nomenclature, or BNA. By JAMES K. YOUNG, M.D., F.A.C.S., Professor of Orthopedic Surgery, Philadelphia Polyclinic; Associate Professor of Orthopedic Surgery, University of Pennsylvania; Orthopedic Surgeon to the Philadelphia General Hospital; Fellow the College of Physicians of Philadelphia; Fellow of the Philadelphia Academy of Surgery; Fellow of the American Orthopedic Association; Member of the American Medical Association, etc., etc. Fifth Edition, revised and enlarged, with 154 engravings, some in colors. Price, $2.00. Philadelphia: F. A. Davis Company, 1917.

As the title implies, this book is a compend of anatomy and the author has succeeded admirably in condensing the great mass of anatomical facts into a comparatively small volume without sacrificing thoroughness for brevity. While the paper and print, as well as some of the illustrations, leave much to be desired, yet in a book of this type what one seeks is facts, generally in a hurry, and so can dispense with the embellishments of the printer's art. The incorporation of the Basle nomenclature is a commendable feature, as all of the larger standard anatomies have adopted this system. The chapters on Surgical and Dental Anatomy are of timely importance. Such a handbook is primarily intended for students and those preparing for State and other examinations, for which purpose it can be recommended.

THE SURGICAL CLINICS OF CHICAGO. Vol. I, No. 3. Octavo of 231 pages, with 70 illustrations. Published Bi-monthly. Price per year, $10.00 net. Philadelphia and London: W. B. Saunders Company, 1917.

THIS issue contains clinical lectures by twenty-one surgeons and many of the articles are of more than ordinary interest. Among these may be mentioned Bevan's discussion of esophageal diverticula, with the technique of the Sippy-Bevan operation for the cure of this condition, and also his remarks on diaphragmatic hernia with description and illustration of technique in one case; McArthur's cases of thrombo-angiitis obliterans, with description of his modification of Koga's technique; Eisendrath's discussion of gunshot wounds of the skull; Phemister's case of reconstruction of the hepatic duct; Case's comparison of the operative and radiotherapeutic treatment of uterine myomas, and the description and illustration of George G. Davis's operation for the cure of hallux valgus. We would suggest to the editor that readers of The Clinics will take it for granted that before an abdominal wound is closed all sponges and pads are accounted for; hence the frequent repetition of this detail seems to be quite unnecessary.

THE SENSE OF TASTE. By H. L. HOLLINGWORTH, Ph.D., Associate Professor of Psychology in Columbia University, and A. T. POFFENBERGER, JR., Ph.D., Instructor in Psychology in Columbia University. Price, $1.25 net; postage, 12c. New York: Moffat, Yard and Company, 1917.

THIS volume is one of a number which make up the "Our Senses Series." The sense of taste has been relatively neglected in its relations to æsthetics and art, although largely utilized in certain occupations. The mere fact that the index catalogue of the Surgeon-General's Office, Second Series, does not contain a single reference to our recent monograph on this subject, should itself be a sufficient reason for the existence of this work. The subject matter of the early chapters of the book is old and can be found in standard reference works. As we progress we note material from Titchener, the psychologist; Pawlow, the psychologist, and Cushing, the surgeon, who are comparatively recent writers. Ramsay, the physicist; Graham and other writers on the chemistry of colloids; Richet and Cannon, physiologists, have all made recent contributions to our knowledge of taste. Writers on comparative physiology have supplied much useful information on the nature of taste perception. The concluding chapter is devoted to the esthetics of taste. It is, therefore, apparent that the authors have drawn their material from all possible sources, old and recent, and from the branches of science which deal with biology, biochemistry and chemical physics; from psychology and anthropology; from clinical medicine and surgery, industries, every-day life. The data are so treated as to make a very interesting and instructive work for all reading people.

DANGERS IN NECKWEAR. By WALTER G. WALFORD, M.D., author of "Cerebral Congestion and Tight Neck Clothing," etc. Price, 4 shillings. London: H. K. Lewis & Co., Ltd., 1917.

THE author of this little work is evidently an enthusiast who sees in tight neckwear an occasional cause of many evils, which depend perhaps in part on predisposition or the action of other factors. The book may be worth reading once for its suggestiveness, and in general diagnosis the examiner should certainly make sure that his subject does not wear too tight collars, etc., which is sometimes done for esthetic reasons.

L'EXPLORATION RADIOLOGIQUE DES VOIES URINAIRES. Lithiases et Projectiles de Guerre. Par le Dr. ARCELIN, chef de service de radiologie à la l'Hôpital Saint-Joseph et à l'Hôpital Saint-Luc. Avec 123 figures et planches hors text. Prix 6 francs. Paris: Masson et Cie., 1917.

IN this compact little treatise, simple radiography of the kidney and pyelography are considered in advance of indiography for lithiasis. There are numerous illustrations of renal and ureteral calculus shadows in association with the shadow of the opaque sound. The statement is made that the stones are sometimes detected during pyelography, but this feature is not illustrated.

In radiography of the urinary apparatus in bullet wounds the ureteral and vesical sounds are often passed to aid by their shadows in locating the exact site of the projectile. The technic for location of the latter is apparently much more simple than in urinary radiography in civil practice—at least, its consideration requires far less space. There is a brief concluding chapter on radiography for foreign bodies in the urinary apparatus.

SOME PERSONAL RECOLLECTIONS OF DR. JANEWAY. By JAMES BAYARD CLARK. New York and London: G. P. Putnam's Sons, 1917.

THIS little tribute to Dr. Janeway was the result of an insistent impulse to memorialize a physician believed by many qualified observers to have been the "best diagnostician in the world." The author began his association with Dr. Janeway as his laboratory office assistant, and at a later period had his office in the Janeway residence; moreover, he had the rare privilege of taking part in his "table talk" (perhaps Stevenson would have characterized the talk as a "rich silence," for Dr. Janeway was not a loquacious man). Through the anecdotal plan Dr. Clark brings out the personality of his hero—his enormous energy, self control, devotion to duty, loyalty to his colleagues, indifference to material wealth, contempt for the pettinesses of life, dislike of publicity which seemed in any way "forced" (he even disliked writing medical papers). His Christianity was of the type that is lived day by day. We can only regret that Dr. Clark did not make his book more comprehensive. Let us hope that some day he will feel impelled to become Dr. Janeway's biographer.

RIVERS AS SOURCES OF WATER SUPPLY. By ALEX. CRUIKSHANK HOUSTON, M.D., D.Sc., F.R.S.Ed., Director of Water Examinations, Metropolitan Water Board. London: John Bale, Sons & Danielsson, Ltd., 1917.

THIS work is a reprint in part of several journal articles and appears to be a successor to a monograph "Studies in Water Supply" which was published 1913. The present volume contains comparatively recent matter in the form of a chapter on sterilization published for the first time. The author sums up by stating that he is not pledged to any one form of water purification. The war has taught us to place efficiency above questions of sentiment. As for sterilization, it has recently been shown that liquid chlorine, so much vaunted of late, is not superior to bleaching powder.

Society Reports.

AMERICAN ASSOCIATION OF OBSTETRICIANS AND GYNECOLOGISTS.

Thirtieth Annual Meeting Held at Newark, N. J., September 17, 18 and 19, 1917.

THE PRESIDENT, DR. JOHN W. KEEFE OF PROVIDENCE, RHODE ISLAND, IN THE CHAIR.

(*Concluded from page 657.*)

The Left Fallopian Tube and Intestinal Stasis.—Dr. DOUGLAS H. STEWART of New York City said that no matter what the nature of the abdominal operation, a conceded genococcus infection might set up a salpingitis and an ileus even though an uneventful recovery might appear fairly certain. His essay not only had nothing to do with such a state of affars, but on the contrary was based upon the histories of two patients whose Fallopian tubes showed no change except such as might be expected to occur from an excess of nutrition; when a portion of such tubes adhered to the anterior wall of the rectum, formed a band there, obstructed the fecal flow and at the same time derived a new and an additional source of blood supply. Such an obstruction might be differentiated from Houston's valve because it was rigid and unyielding and because it was so plainly not within the lumen, but it was very evidently on the outside of the rectal wall. By it the bowel was converted from a more or less perfect cylinder into a cross-section that might be schematically represented by an arc and its chord. As a result of fatigue and muscular exhaustion that were due to the constant if partial resistance of the obstacle, that bowel ballooned both above and below the band. The author did not think that the condition was necessarily rare, for any surgeon coming across it during his exploration of an abdomen, would simply term it a band, would cut it and would relieve all the symptoms, without troubling himself to determine the nature and origin of that band, or even to dignify it with its proper anatomical name. Both of the cases reported were in patients who were well past the menopause, yet the new blood supply, that was derived in a sort of parasitic manner, prevented atrophy of that portion of the tube that had become adherent. Removal of the hypertrophied section relieved all adverse symptoms by freeing the gut and allowing it to resume its functions unhampered.

The Ductless Glands in Gynecology and Obstetrics.—DR. SAMUEL W. BANDLER of New York City stated that the action of most of the internal secretory glands of the body was now fairly well understood. Therapy that was most efficient in hyposecretion was not so efficient in cases of hypersecretion. Gland therapy was more difficult if more than one gland was upset in the cycle. If the whole cycle of glands was upset, therapy was doubtful. The value of gland extracts was much enhanced by the use of drugs which had been tried and found of value. Thyroid extract and ovarian extract so far had been proved most successful when administered by mouth and by hypodermic. Gland extracts were of value for diagnosis.

The Thyroid in Gynecology.—Dr. HERMAN E. HAYD of Buffalo reccommended thyroid extract in the treatment of the ill-determined hemorrhages of women, where the causes were obscure, until a diagnosis could be established and the best kind of subsequent treatment decided upon. In this connection he wished to report the following case:

Mrs. S., aged 43 years, three children, oldest 13, youngest 5. She had always bled freely at her periods, and at some times profusely; but for the past ten months, she was compelled to wear a napkin all the time because of the continuous dribbling and loss of blood, and at certain times she had to go to bed, as the hemorrhage was excessive. Her brother, a physician, sent her to Dr. Lothrop, who prescribed thyroid extract, and suggested the advisability of a curettage for diagnostic purposes, and then later more comprehensive surgery, if necessary. She did not take this good advice, and continued to bleed until March, when Dr. Hayd, who had taken care of her in her first two confinements, was called. He found her in a very nervous condition—very much swollen and puffy, extremely pale and anemic, dropsical, with loud hemic murmurs, and presenting the usual symptoms and picture of prolonged and exhausting hemorrhages. Upon vaginal examination, the os was found to be closed, and the uterus in good position, and apparently not much larger than normal. A tentative diagnosis of a possible myxedema was made, and thyroid extract in increasing doses was given. At once, the bleeding became less, strength and better feeling began to return, and after four weeks another vaginal examination was made, when the os was found open, and a myxomatous polyp, the size of a small plum, was protruding, which was easily removed without any anesthetic; the woman very quickly regained strength, and was now well, with good color, full of energy, and weighed 160 pounds. The thyroid in two-grain doses was continued, with five-grain Blaud's pills, modified, for some weeks. He did not believe it was a mere coincidence that this polyp was found expressed out of the uterus during, but independent of, the thyroid treatment; because the bleeding was at once influenced and notably decreased after a few days of thyroid medication.

This case he had reported at length, because of its pronounced and somewhat dramatic result, and yet he could detail a number of encouraging experiences in the treatment of prolonged menstrual bleeding with thyroid therapy, when a previous curettage did not bring about the expected relief. Perhaps some of these cases were due to a general fibrosis of the uterus, or to some disturbed circulation in the organ, and not to a thickened and softened endometrium where curettage was usually effective. In the amenorrheas of young girls, where the periods were irregular or scanty, and even absent, or where the menstrual function had not appeared at the usual pubic period, he had of late years relied upon thyroid feeding, in gradually increasing doses; of course, in conjunction with good hygiene, and proper living and exercise; and here he could detail the histories of many cases where menstruation was established after having been absent for months, or where marked irregularities existed, and normal function was brought about.

Interrelationship of Female Sex Glands and Pituitary.—Dr. JAMES E. KING of Buffalo said that the literature of the ductless glands was at present concerned largely with theory. Cushing's work had done much to add to our understanding of pituitary pathology. There were disturbances of secretion which were not dependent upon cellular pathology. These would show varied clinical manifestations which, after further study and observation, it would be possible to classify. In the study of the physiology of the ductless glands, the interrelationship of all must be kept in mind. The pituitary influenced metabolism in growth of bone and disposal of the carbohydrates. Its influence upon the sex organs had been repeatedly demonstrated, and it was an important factor in the phenomena of puberty and in the sex life of women. The secretion might also influence mental characteristics, as seen in the hyper- and hypostages of acromegaly. The clinical picture of the less evident forms of pituitary dystrophy would vary somewhat with the age when the perversion occurred. Occurring before puberty, menstruation either failed to appear, or was irregular and scanty, and there was evidence of disturbed carbohydrate metabolism. A diagnosis of infantile uterus was usually made. The perversion occurring after puberty was evidenced by menstrual disturbance and rapid increase in weight. A type deserving place as a clinical entity were those women who were married and suddenly gained greatly in weight, with menstrual disturbance or amenorrhea. They were obsessed by a belief in their pregnancy. There was high sugar tolerance. It was suggested that this syndrome be designated as the pseudocyesis of hypophysical dystrophy. The possibility of maternal love in the lower animals being the result of pituitary secretion was suggested. The therapeutics of glandular perversions at present were unsatisfactory. Success would be attained only after a better understanding of the physiology of the endocrine system.

President's Address.—Dr. JOHN W. KEEFE of Providence, R. I., said that it would not be difficult to show,

from the history of medicine, that the education of the mind had always accompanied the education of the hand; the hand being, to adapt a phrase of Burdon Sanderson's, "The scientific instrument of the surgeon." So true was this that when the mind languished the cleverness of the hand was proportionately diminished, and when the hand failed in its ministrations the mind ceased to grow, and so it was that the surgeon, if he would be a skillful craftsman, must of necessity be first a skillful thoughtsman. For in what consisted the surgeon's manual dexterity if it be not in the deft application to the diseased human body of the principles of anatomy, physiology, and pathology; converting his concepts into acts, he thus became, as it were, the mediator between the theories of the schools and the lives of his patients. Let us, therefore, banish from our minds, if indeed we ever entertained it, the superficial and quite erroneous view that mechanical facility alone was the chief attribute of a successful surgeon. How far, think you, would mere manual dexterity have carried a Murphy, a McBurney, a Bigelow or a Senn, did they not possess also the wide sweep of intellectual vision which opened to them hitherto unexplored fields for research and gave them that mental alertness which was the prerequisite of their notable achievements. The hand, the eye, the mind, working in mutual helpfulness, constituted the ideal surgeon as he was trying briefly to picture him. The limitations of our human facilities and abilities compelled us to a division of labor, and here lay the pitfall that beset our progress. Our constancy to one thing too frequently spelled neglect of the rest, and the very intensity of our vision narrowed the sweep of it. In this tragic world war, when man's inhumanity to man made countless thousands mourn, when human life was held at naught, and human brains were racked to devise new instruments of destruction, each more deadly and revolting than the other; was it not comforting, nay inspiring, to feel that there was in the world a thoughtful and earnest body of men who, imbued with high ideals, were ministering to the wants of friend and foe alike; who feared nothing so much as failure in service, and who constantly endured great personal sacrifices to increase their knowledge of science, to the end that its beneficent ministrations to the sick and wounded might return them again to health and happiness.

The Influence of Pregnancy on the Development, Progress and Recurrence of Cancer.—Dr. WILLIAM SEAMAN BAINBRIDGE of New York City cited two cases of malignancy in pregnant individuals which bore a distinct relation to the question of the possible influence of pregnancy upon the initiation, progress, and recurrence of cancer. In the first case, recurrent carcinoma of the breast, there was a previous history of amputation of the right breast fourteen months earlier. When first examined, the patient, a primipara, was nearly five months pregnant, and had a large mass in the right axilla and another above the clavicle, with metastases in the right lung. The patient and family refused to submit to the termination of pregnancy, and despite indicated treatment the disease extended rapidly and fatally in less than a year. The child was born at term and lived one month. In the second case, sarcoma of the eye, the patient, a mother of two children, was pregnant seven months when first seen. At this time she had a small growth which was promptly excised with an apparently safe margin of healthy tissue. There were three other successive operations for rapid recurrences and extension of the disease—all within a period of two months. Termination of the pregnancy had been refused and a healthy child was born at term. One month later the patient succumbed. In the first case the growth above the clavicle was probably not malignant until pregnancy took place; from the history of the second case it would seem as if the beginning of the development of the sarcoma was closely related to the beginning of the pregnancy, and that the almost terrific rapidity of development and recurrence after operation was commensurate with the progress of the pregnancy. From these and other personal observations, as well as from a digest of the literature, it was apparent that the weight of opinion from the clinical and experimental points of view substantiated the position that pregnancy exercised a stimulating, and hence a malign influence upon coexistent cancer, not only of the organs most closely concerned in the pregnancy, namely, the uterus and breast, but of any part of the body. Therefore, in all such cases, especially in those similar to the second, there seemed little ground for delaying or for failing to terminate the pregnancy as early as possible. It was interesting to note in this connection that relatively little attention seemed to have been devoted to the question of the influence of pregnancy on the development of cancer, other than cancer of the uterus and breast, particularly the former.

Treatment of Appendicular Abscess.—Dr. W. A. B. SELLMAN of Baltimore stated that the important features in the treatment of appendicular abscess were: (1) To bring the sac up and wall it off so that the purulent fluid might not infect the surrounding tissues; to secure drainage after being emptied at its most dependent portion; to prevent choking and obstruction of these drains. (2) Protect the healthy parts by using rubber tissue around drains and upon the skin around the abdominal wound. Change the fluff gauge whenever it had become saturated with the discharges. Do not withdraw drains until satisfied that they had accomplished all that could be secured by their use. (3) Stimulate granulation and destroy pyogenic tissues by irrigation. Keep the patient in the most favorable position to secure drainage. (4) If we found the appendix and intestines showing evidence of gangrene, and the patient was threatened with shock, refrain from removing the appendix, as many of these cases recovered, whereas if the operation was prolonged they died. In the majority of cases no post-operative symptoms developed. He had patients who had been operated upon five to eight years without their developing any indication for a secondary operation. Experienced surgeons had claimed that 10 per cent. required the secondary operation. His experience did not coincide with those statistics.

Pre-Eclamptic Cesarean Section.—Dr. JOHN WILSON POUCHER of Poughkeepsie, N. Y., stated that statistics of puerperal eclampsia showed unsatisfactory results. When a patient at or approaching term, in spite of all means of elimination, showed us by nervousness, sleeplessness, severe headaches, high blood pressure, edema, and excessive albuminuria, that convulsions were imminent, she should be delivered at once, and by the method which would cause the least delay and which would produce the least shock, and give both mother and child the best chance for recovery. Since 1914 he had done seven pre-eclamptic cesarean sections. Of these, all seven mothers and eight children survived, one mother having twins. Two were operated after labor had begun, five before the beginning of labor. Two suffered postpartum convulsions, two having two convulsions, the other one convulsion, which were easily controlled. It was constantly pointed out that the scar of a cesarean section was likely to weaken the uterine wall and subject the patient to the danger of a possible rupture of the uterus in any subsequent labor. This could not be denied, but which was the greater of the two evils? One was a very present and very grave danger, and the other was a remote and improbable one.

Toxemia and Eclampsia and Its Treatment.—Dr. ASA B. DAVIS of New York City said that all of his eclamptics were not delivered by cesarean section. He had performed 359 abdominal cesarean sections. In 25 instances, toxemia of pregnancy had been the indication. These 25 cesarean sections had been done on 23 different women. Eight women died. Twenty-nine children were delivered; twins in two cases. One set of twins was dead when the patient was admitted. The mother lived. Nine of the 29 children delivered failed to leave the hospital alive. It was a noticeable fact that few pregnant women in private practice under the care of skilled obstetricians developed eclampsia. The knowledge of this fact and his own experience prompted the statement made early in the paper, "The time to treat eclampsia is before it occurs."

The Conservative Treatment of Eclampsia. — Dr. ROSS MCPHERSON of New York City stated that a thoughtful survey of the mortality statistics of patients suffering from eclampsia, taken from the reports of numerous writers both here and abroad, would show that treated by radical methods the maternal mortality approached an average of from 25 to 30 per cent., these

figures being easily available, and that the fetal mortality averaged from 40 to 50 per cent., surely a frightful complication, the etiology of which no one knew, a fact most constantly impressed upon him by reading the numerous dissertations of various authors on their experimental work. His series now included 55 true convulsive toxemias. Of these 55, 7 mothers died, showing a gross maternal mortality of 12.7 per cent. Two of these mothers, however, died before treatment of any sort could be administered, one arriving post-partum at the hospital, and dying before anything could be done for her, the other dying of cerebral embolus while apparently in good condition, and after having had but one convulsion. In these two cases no form of treatment whatever would have been successful, so that in a comparative estimate of methods of treatment it was fair to exclude these two patients. Then this left a corrected mortality of five mothers out of 55 patients treated in the manner already described, namely, by conservative measures, or in other words, a mortality of approximately 9 per cent. Abdominal cesarean section, he believed, had absolutely no place in the treatment of convulsive toxemia of pregnancy except in the cases where the eclampsia was accompanied by a deformed pelvis or some severe disproportion between the mother and child. More conservative measures could be resorted to with a lower mortality.

The Indications for Interference in Pre-Eclamptic Toxemia.—Dr. WILLIAM G. DICE of Telodo, Ohio, said that eclampsia was the greatest danger confronting pregnant women. The character and quantity of the waste products from a study of urine were not definite indices of severity of the toxemia. The systolic blood pressure taken throughout pregnancy was ordinarily a better index. A steadily increasing rise from the average normal, 110 to 120, up to 150, was significant and there was a sudden increase in the evidence of toxemia when blood pressure reached that point. Elevated blood pressure often preceded albuminuria, and the two were not necessarily proportional. When the blood pressure reached 170, if other signs of toxemia were also present, time for expectant treatment was near an end. Few men appreciated the importance of eye symptoms as an index of toxemia. Toxins in the blood gave rise to a retinitis, the first symptom, objectively being edema, later infiltration, degeneration and hemorrhages or, perhaps, detachment of the retina, and both latter indicated grave toxemia. In the early stage of retinitis, the vision might not be affected, but the ophthalmoscope showed a haziness of the fundus, an inability to make out the fine details which was the first sign of cloudy swelling. The interference with vision depended upon the location of the lesion, whether in the macula or only in the areas surrounding it. The condition cleared up entirely if it did not go beyond the stage of cloudy swelling. In primiparæ this haziness of the retina was easily detected if the pupil was widely dilated, and this haziness was the first indication of retinitis, but if there had been previous eye trouble it could not be made out so early probably. Conservation of vision, as well as life, demanded prompt induction of labor.

The Alcohol Drain in Septic Cases Requiring Cesarean Section.—Dr. CHARLES L. ILL of Newark advised that the alcohol drain be applied in all cases of sepsis when a cesarean section had been done. He based his views on an experience of ten cases, all of which were severely septic previous to operation.

The Treatment of Ectopic Gestation with a Report of Twelve Cases.—Dr. ABRAHAM J. RONGY of New York City stated that repeated ectopic pregnancies were more frequent than was generally supposed. While we all must admit that conservation of the other tube was necessary in women who were operated on for ectopic pregnancy and who had had no children, he felt that to patients suffering from ectopic pregnancy and who had three or more children should be explained the danger of a repeated ectopic pregnancy, and with their consent the tube on the other side should either be ligated or resected.

Should the Uterus Be Removed When It Became Imperative to Interrupt Pregnancy?—Dr. EMERY MARVEL of Atlantic City, N. J., said that the interruption of pregnancy was accepted only when maternal life was seriously jeopardized. The exciting cause was active within the uterus and involved the uterine structure. To remove the conception and leave the uterus when serious toxemia existed left a major part of the burden that could be removed. If the uterus was permitted to remain it invited the recurrence of the condition and in a more aggravated form. If maternal life was threatened by coexisting maladies—such as tuberculosis, renal or cardiac inefficiency—hysterectomy protected against recurrence. The removal of the uterus eliminated the necessity for sexual abstinence. Hysterectomy secured greater freedom from the menace which immediately threatened; it protected against recurrence of the trouble, and provided for the continuance of the sexual life without fear and all that it involved. This could be accomplished with no increased risk over other surgical methods.

Retained Secundines; A Study of Etiological Factors.—Dr. JAMES E. DAVIS of Detroit said that the etiological causes of abortion and early miscarriage must be closely studied in arriving at an appreciation of incomplete abortion. Why should the natural processes usually inadequate in expelling the products of conception in its early period succeed so efficiently at its maturity? The disproportionate growth of ovum and secundines had an undoubted influence upon the uterine mechanical effort at expulsion. The influences of infection, embolism and other circulatory changes, the various traumata and pathological uterine tissue changes, especially those following previous abortions after producing an expelling force were exerted primarily upon the ovum. An understanding of the prevailing changes in the products of conception and their influence upon expulsive force would emphasize the indications for efficient treatment of this condition.

Notes on Methods for Overcoming Mechanical Obstruction to Pregnancy.—Dr. ROBERT T. MORRIS of New York City said when observing the work of various operators one was struck by their differences in attitude toward mechanical obstacles to pregnancy. Some surgeons entered into painstaking technical detail in a conservative way, while others made short work of some symptom-producing obstacle, without regard to conservation of organs. One operator would remove a fibroid tumor, or an entire uterus, in a case in which another operator would conserve enough of the uterus for repair purposes which would allow the patient to have, at least, one child before recurrence of degenerative change of the uterus. Several forms of salpingitis left mechanical obstruction to pregnancy because of adhesions, or of closed lumina between ovary and uterus, but in a certain proportion of selected cases the buried fimbriated end of an oviduct might be freed and grafted near the fundus of the uterus, thus making a short circuit past adhesions or a closed lumen. At present he had a patient about to be delivered of a child who had only one such oviduct allowing of plastic repair of this kind. Perhaps the most extensive plastic work which he had done was for a patient who had lost both ovaries and tubes some years previously; in that case he first grafted an ovary from another patient, and about a month later reopened the abdomen to determine if the graft appeared to be in good condition. This was the case and a new oviduct was constructed from a transplanted loop of ileum, one end of which encompassed the engrafted ovary, the other end being sutured to the walls of the open lumen of the uterus. There had been no practical result in this latter case, and it might be that the mucous secretion from the bowel transplant might interfere with impregnation. But the work might at least, be done experimentally for a patient who understood and accepted the work upon that basis.

Version, with a Report of 150 Cases Since September, 1916.—Dr. IRVING WHITE POTTER of Buffalo stated that version could be more often performed to shorten labor, to lessen the shock to the mother, to eliminate undue pressure to the head of the child, but it should never be undertaken until the os was fully dilated or dilatable. The majority of occipitoposterior positions were best treated by version. Version could readily be performed in primiparæ. The fetal mortality in version should not be as great as in prolonged instrumental delivery. Injuries to the child's head were lessened by a properly performed version. The face cases were better treated by version. Cases of prolapsed cord, where the cervix was dilated or dilatable and the cord still pulsating,

were best treated by version. Cases of placenta previa in multipara, with cervix dilated or dilatable, were best treated by version. Cases of moderately contracted pelvis with a small child were best managed by version.

A Further Study of the Use of Chloroform in Labor.—Dr. I. L. HILL of New York City said that in June of last year he reported to the American Medical Association the results of his animal experimentation and clinical experience, as well as an exhaustive study of medical literature, and came to the conclusion that there was no analogy between such experimental work as had been done on animals and the careful administration of therapeutic doses of chloroform in labor. He had been surprised at the tendency of obstetricians to discredit the use of the anesthetic that had been most useful in their practice, not on the evidence of what had occurred in obstetrics, but what had been found at times in deep surgical anesthesia, and what was reported from animal experimentation. It would be reactionary and contrary to the purpose of scientific advancement to ignore the evidence of the laboratory. It seemed only practical, however, to study the reasons for the apparent discrepancy between obstetrical experience and laboratory findings and also between the use of this narcotic in labor and in general anesthesia. For the analgesia of labor chloroform correctly used was perfect in results and absolutely safe. Other men had found great satisfaction in the use of nitrous oxide oxygen, and it seemed that as they became skilled in its use they obtained a satisfactory analgesia just as he did with chloroform. It could not be safer, however, and its exponents must not seek to establish it on the basis of experimental poisoning of animals with chloroform, nor on the use of chloroform in surgery for complete anesthesia. For neither had any bearing on the harmless chloroform analgesia of obstetrics.

Diagnosis and Management of Narrow Pelvis.—Dr. E. GUSTAV ZINKE of Cincinnati said that the doctrine of narrow pelvis was not sufficiently understood, and its therapy was practised by comparatively few. Four degrees of narrow pelvis were generally accepted. The treatment in the first and second degree of pelvic contraction was not so easily determined. Rules for treatment in the two highest grades of contraction were very simple. Points of diagnosis must guide us in our judgment of cases and assist us in determining the treatment to be adopted. The high forceps was justifiable only when the head was well flexed and fixed in the pelvic brim. In his paper he discussed prophylactic version, craniotomy, hebosteotomy, or symphyseotomy, also abdominal cesarean section.

A Case of Gangrene of Uterine Fibroids Following Parturition; Panhysterectomy.—Dr. RALPH WALDO of New York City stated that the specimen which he showed was removed from a colored woman, aged twenty-four. In performing panhysterectomy every possible care was taken to protect the neighboring structures and the abdominal wall with gauze sponges. The upper end of the vagina and the abdominal wall were closed. The morning following the operation the temperature was 99.6° F., but during the afternoon it rose to 103.2°, pulse 128, respiration 28. For the next four days the temperature was between 104.4° and 102°, the pulse was between 100 and 156, and the fat in the abdominal wound broke down, a wet bichloride dressing was applied. The women gradually improved until the eighteenth day after the operation when a left lobar pneumonia developed with temperature as high as 104.2°, pulse 158, and respiration 50. This condition lasted for three days, after which all of the symptoms gradually improved, and she was discharged from the hospital cured March 16, 1916. This was a rare complication of parturition; but previous to this it was his good fortune to see two similar cases, and from the experience with these cases, although it was small, he was convinced that early panhysterectomy before the peritoneum was involved gave the patient the best chance for her life.

Osteoma of the Descending Ramus of the Pubes and Ascending Ramus of the Ischium Obstructing the Pelvic Outlet; Pregnancy; Removal of the Osteoma.—Dr. JAMES N. WEST of New York City presented this case on account of the rarity of the occurrence of osteoma in this situation. In three weeks on obstetrics referred to by him in his paper he saw no mention of dystocia from this cause, and in his own examination of women, pregnant and nonpregnant, in his office and hospital work, this was the only one he had seen. In other parts of the body the occurrence of osteoma was not infrequent. The case was reported on account of the rarity of the condition—the extremely satisfactory result of operation, the only adverse circumstance connected with which was the weakening of the pelvic framework of the body. This, however, was in a large measure counteracted by the firm ligamentous structure which had taken the place of the bone and served perfectly for the attachment of the muscles formerly attached to the bone in that situation.

The following papers were likewise read: "The End Results of the Treatment of Inoperable Uterine Cancer by Heat," by Dr. James F. Percy, Galesburg, Ill.; "Left-Sided Appendicitis in Situs Inversus Totalis," by Dr. Julius H. Jacobson, Toledo, Ohio; "The Technique of Ureterovesical Anastomosis, with Moving-Picture Demonstration of Same," by Dr. Henry D. Furniss, New York City; "The Causes of Death in Child Birth: A Discussion of the Maternal Mortalities in 100,000 Confinements at the New York Lying-In Hospital," by Dr. J. A. Harrar, New York City; "A Statistical Study of Maternal Mortality and Early Infant Mortality," by Dr. Julius Levy, Newark, N. J.

AMERICAN PHILOSOPHICAL SOCIETY.

AT a stated meeting held in the hall of the society at Philadelphia on the evening of October 5, Dr. ALEXIS CARREL of the Rockefeller Institute for Medical Research, Major in the French Army, and Chief Surgeon to Temporary Hospital, No. 21, Compiègne, France, presented a communication entitled "Principles of the Treatment of Wounds" with lantern-slide demonstration. He reported the results of an intensive study of gunshot wounds acquired on the French front during the present war, made especially from the bacteriological, surgical, and mathematical points of view, and he described the methods of precision in treatment therefrom evolved. It was found that the course of such wounds and the outcome of treatment varied directly in proportion to the degree of infection, as determined by the number of bacteria in a given microscopic field of smears made from the wound, and charted systematically. The first and most important requirement is mechanical disinfection of the wound at the earliest moment possible by means of free exposure, thorough cleansing and the removal of foreign bodies and adequate and continuous drainage. In addition, various chemical disinfectants were employed in solution, in dry form and in the form of pastes, among these sodium hypochlorite, chloramin T, physiological salt solution. By the employment of the methods described results were obtained that were scarcely short of miraculous in the case of wounds of all sorts in many parts of the body and under otherwise most unfavorable conditions. As a result amputation was avoided in a considerable proportion of cases in which otherwise it would have been obligatory in order to save life.

Captain LECOMTE DU NOÜY of the same hospital presented a communication entitled "The Mathematical Study of the Cicatrization of Wounds." He pointed out that Dr. Carrel had previously described the course of cicatrization in wounds and that the time required could be predicted in accordance with the size and extent of the lesion. On the basis of this knowledge a mathematical formula was devised with the aid of which it could be determined in advance with a considerable degree of precision how long wounds cleared of infection and kept free therefrom would require for the process of healing. An extended series of observations showed how closely the actual accorded with the predicted results. It appeared that apart from infection or traumatism little either accelerated or retarded the course of the process.

Emotional and Commotional Syndromes.—Mairet and Piéron discriminate carefully between these conditions. In the former fright is the sole motivation, a somatic factor being absent. Despite the psychogenic origin the disease does not yield to suggestive therapeutics. These cases of pure emotional shock are rare.—*La Presse Médicale.*

Miscellany.

Swiss Inaugural Dissertations for 1917.—It is not without interest to review the output of the Swiss Universities in the way of medical graduation theses during the third year of the warfare which rages with undiminished violence about the little republic. Should this state of war not react in some manner on the topics selected by the graduates? The fact that no direct evidence of such a reaction is presented inclines us to the belief that such subjects are deliberately avoided. However, in the *Correspondenz-Blatt für Schweizer Aerzte* for August 18 is a list of nineteen graduation theses of the Basle University. Of this number no less than seven are devoted to obstetrical subjects, which incidence may connote an indirect bearing on the results of warfare in destroying manhood and in putting thereby an increased value on infant survival. The remaining eleven subjects are notably individualized.

The small number of graduates in the Universities of Berne and Zürich suggests that Swiss students are seeing service on some of the fighting fronts. But six Berne theses are enumerated, while at Zürich there are only nine. Of this material of fifteen, three are devoted to purely biological themes, the dominant practical subjects being pediatrics and syphilis, these comprising nearly all of the remaining material. This great predominance of obstetrical and pediatric subjects with syphilis may represent an unconscious reflex of post-bellum demands in Europe for concerted effort in the domain of repopulation.

A British Ministry of Health.—The following plan has been proposed to the British Government by the Council of the British Medical Association: A ministry of health should be created to take over from existing government departments such duties as are concerned with the health of the community, and to deal with those duties only. The administrative functions of the ministry should be carried out by a board presided over by a minister of Cabinet rank. The country to be divided into suitable administrative areas under local administrative health centers consisting of representatives (a) of the rating authorities; (b) of the education authorities; (c) of the persons contributing to a scheme of health insurance (including employers of labor); (d) the medical profession; (e) public hospitals; (f) dentists; (g) pharmacists, and (h) nurses. The principal medical officers of each center should be two, of equal status, one representing the clinical side (chief clinical officer) and the other the preventive side of medicine (medical officer of health). For each area, hospitals, clinics, or treatment centers should be recognized or established at which persons entitled to treatment under the public scheme should be able to obtain institutional, consultative or specialist services on the recommendation of their medical attendant.

The Depopulation of France.—The war with its destruction of the man power has exposed more clearly than ever the danger to the future of the country lying in the declining birth rate. A committee of the Academy of Medicine of Paris has suggested as a possible remedy the payment of a definite sum to every infant from birth to the time of the eruption of its twentieth tooth.

Therapeutic Hints.

Care of the Foot.—Harold D. Corbusier offers the following suggestions which have been brought forth with reference to the care of the army foot: "Weak foot" may be relieved by the French marching strap, which is placed under the shank of the shoe, crossed over the instep and then around the ankle and fastened. In most cases the wearing of a shoe constructed on the proper principles will avert the feeling of pain and depression of the long arch which accompanies the "weak foot," or will cure the condition when developed. Such a shoe should have a thick shank and the upper should be snugly fitted under the long arch.

Blistering of the feet may be relieved by the application of a 3½ per cent. solution of iodine, opening the blisters with a sterilized needle and then applying a small dressing of gauze or cotton with adhesive plaster. Socks should be of wool. Foot powders composed of stearate of magnesia or zinc should be applied freely. However, a greasy powder, non-irritating, is more effective in the prevention of blisters than a perfectly dry powder. Socks must be perfectly clean. A well-fitting shoe usually relieves all foot troubles, together with perfect cleanliness of the parts.—*American Medicine*, May, 1917.

Tar in the Employment of Skin Conditions.—Pusey recommends Bulkley's formula for tar as a remediable application in skin conditions of the subacute varieties:

℞ Pix liquida.....℥ij
Potassa caustica .....℥j
Aqua .....f℥j
—Principles and Practice of Dermatology.

Bad Breath from Mercurial Salivation.—

℞ Pulv. aluminis .....℥ss
Decocti quercus albæ.....℥viii
M. Sig.: Use as a mouth wash every hour.

Spongy Gums.—

℞ Tinct. myrrhæ.....℥iii
Infus. cinchonæ.....ad ℥iv
M. Sig.: Apply thoroughly with camel's-hair pencil to gums three times a day.

Vaccine Therapy for Whooping Cough.—C. J. Bloom gives the following dosage of pertussis vaccine as productive of curative results.

Bordet-Gengou bacillus	50,000,000
Staphylococcus pyogenes aureus	10,000,000
Micrococcus catarrhalis	20,000,000
Bacillus influenzæ	20,000,000
Streptococcus pyogenes	20,000,000

The first dose must not be less than 120 million; this is increased 60 million for each succeeding dose and the maximum quantity given every other day until one of the marked symptoms shows an appreciable improvement; continue every three or four days after signs of improvement.

Vaccine is the preferred treatment because no reaction occurs. The duration of symptoms averages usually only twenty-eight days with this form of treatment, and the loss of weight is very small —14 ounces; after the third injection the attacks of coughing are reduced in number and intensity; sleep is not disturbed after from five to twelve days, and no complications have appeared in the cases so treated after from eight to twelve months' duration.—*Practical Medical Series, Vol. V*, 1917.

THE RELATION OF THE SPLEEN TO CERTAIN OBSCURE CLINICAL PHENOMENA.*

BY WILLIAM J. MAYO, M.D.,

ROCHESTER, MINNESOTA.

THERE is a fascination about the study of the spleen in its relation to clinical medicine which is increased by the fact that those twin sisters of progress, pathology and experimental medicine, have contributed so little to our knowledge of the organ. The result has been that what we know and what we think we know about the spleen is largely the result of circumstantial evidence having its origin in comparative anatomy and physiology, and the results of clinical experiences capable of different interpretations. As the spleen has no external secretion and no known internal secretion, the results of its actions cannot be studied directly. We know that the removal of the normal spleen rendered necessary by traumatism, etc., introduces no serious bodily change. In practically all the diseases in which splenectomy is thought to be indicated, the spleen is enlarged, and this enlargement, on account of the concealed situation of the organ must be very considerable, perhaps twice the normal size before we can know that the enlargement exists. Palpation gives the only definite information as to the size of the spleen; if it cannot be felt, percussion is a poor and misleading substitute. Much may be expected from the roentgenogram in the future to make manifest the size and position of the spleen as it has so satisfactorily done with the kidney. We are as yet unable to study the earlier manifestations of associated diseases in relation to the size of the spleen; and its lesions are gross before we can be certain that it is concerned in the production of the symptoms from which the patient suffers. Another source of uncertainty arises from the fact that the spleen alone is seldom responsible for the production of the clinical phenomena. It is more often the agent than the cause of the illness. In the 168 cases in which we have removed the spleen, it was surprising how many diverse clinical conditions were represented and yet how little the pathologic diagnosis varied. No matter how widely the clinical phenomena differed, the spleens on both gross and miscroscopic examination showed changes varying chiefly in degree; that is a more or less marked fibrosis, a greater or a smaller amount of degeneration of the blood vessels and Malpighian bodies, or a hypotrophic or an atrophic spleen pulp.

*Wesley M. Carpenter Lecture, New York Academy of Medicine, New York City, Oct. 18, 1917.

Cell study of fresh splenic tissue by special methods is needed and gives promise of more definite pathological comparisons.

Accepting then the necessity for securing what knowledge we may from collateral evidence, an investigation of the facts, near-facts and fancies, taken as a whole may throw considerable light on the subject.

The spleen is derived from mesoblastic tissue, and is probably concerned largely with filtration of certain substances from the blood and the product of its activities is delivered to the liver through the splenic vein, suggesting at once what clinical experience has shown—its relation to the blood and to the liver. It may perhaps be most aptly compared to the kidney, also derived from mesoblastic structure, and also without true secretion, a filtering organ. Cushny well expresses the modern view that the kidney has no true secretion, but that it filters certain substances from the blood in proportion to the absolute amount in the plasma, so-called no-threshold bodies and other threshold bodies only when their percentage in the plasma exceeds certain values.

The normal spleen weighs 195 grams (Sappey). It has a very scanty nerve supply from the sympathetic system, but it does contain a considerable amount of non-striated muscle fiber. Keith has demonstrated that the non-striated muscle has the power of originating contractions independent of nerve supply and exhibits a most primitive form of control. This attribute is shown wherever non-striated muscle is to be found. The intestine, like the heart, has two beats, the first once or twice to the minute, which we call peristalsis; the second, 12 to 20 times to the minute, which acts as the heart of the portal circulation (Mall). The spleen has what might be called a beat which consists of an enlargement following food intake with a gradual resumption of its normal size after several hours, showing a definite connection with the digestive function, which is indicated again by the fact that its blood supply is from the celiac axis, the same source of supply as that of the derivatives of the foregut, the stomach, the liver and the pancreas. Elliott and Kanavel have shown that the intramuscular injection of epinephrin contracts the spleen one-third in size.

The blood entering the spleen is peculiar inasmuch as it comes in direct contact with the splenic pulp, the smaller blood vessels having lost their elastic coats. This renders the spleen fragile and leads readily to traumatic or spontaneous rupture resulting in intraperitoneal hemorrhage or hematoma within the splenic substance. The latter con-

dition results in cyst, the most common type of tumor of the spleen (Powers). This peculiarity of the blood vessels also renders the spleen extraordinarily susceptible to the influence of radium which acts with vigor on the single coated blood vessels, non-striated muscle and the nuclei of cells. It may be surmised that the spleen does not possess an internal secretion of importance not only because removal of the normal organ does not disturb the body metabolism but also because of its extremely limited sympathetic nerve supply. It is to be noted that the organs of primary internal secretion usually act through the sympathetic nervous system. The adrenals and the pituitary are so closely connected with the chromophil system that their union amounts almost to a single organ, half sympathetic and half secretory. Other organs like the thyroid (Plummer, Kendall), gonads, pancreas, etc., which have internal secretion acting to a large extent through the blood stream had at one time or still possess an external secretion as well as an internal. The spleen does not properly fall into either of these categories.

On hypothetical grounds it seems probable that the spleen develops certain enzymes which are important to its function, but it is equally evident that the function of the spleen is shared by other lymphoid and adenoid structures in the body, and that on the removal of the organ the function is continued by these collaborating structures (Warthin).

It has been suggested that the spleen is a retrogressing organ. The outstanding factor of a retrogressing organ is diminished blood supply (Eccles). The blood supply of the spleen is enormous and it may be readily seen that a large percentage of the blood of the body passes through the spleen every hour.

Relations of the Spleen to the Blood.

The blood may properly be termed a tissue, consisting of erythrocytes, leucocytes, and platelets, in which the plasma is a fluid medium taking the place of intracellular substance. The white blood is the most primitive, derived from the mesenchyme cell. The earliest heart was possibly a lymphatic heart, circulating white blood, which merged later with the venous heart, leaving among other evidence the lymphatic connection of the thoracic duct with the venous system. Animals which have only one kind of blood have white blood. The fetal blood is produced by the lymphoid and adenoid structures of the body, including the liver and spleen. From this standpoint, leukemia could be considered a cancer of the blood in which there is an uncalled-for production of functionless white cells, just as carcinoma is due to the unlimited production of embryonic epithelial cells and sarcoma of embryonic connective-tissue cells. The earliest blood discovered in the fetus is the white, and the red cells are probably derived from the white cells. The spleen loses its power to produce red blood at birth and the liver at about the fifth fetal month, but the spleen retains its power for a limited production of white cells throughout life and assumes the function of the destruction of worn-out red cells which is shown by a relative increase in the white cells and of hematin in the splenic veins over other veins in the body.

When the spleen is removed in certain enlargements, as in hemolytic icterus, it is found crowded with erythrocytes in various stages of disintegration and we know that the specific splenic cells have phagocytic properties. Robertson and Rous, in a study of the relation of the spleen to the blood, have come to the conclusion that fragmented erythrocytes are not only removed there but that fragmentation must take place in the spleen. Normal fragmentation depends on the natural life of the erythrocytes, which has been estimated at from ten to fourteen days. This estimation has been made largely on the assumption that biliary pigments are derived entirely from the destruction of erythrocytes. Whipple and Hooper, by a series of careful experiments, throw considerable doubt on the view that the biliary pigments have no other origin than from destroyed erythrocytes and it is quite probable that the life of the red cell is much longer than has been estimated. In some of the anemias, notably hemolytic icterus, Shauffard and Widal show that the erythrocytes circulating in the blood are unusually fragile and that this fragility leads to undue fragmentation and destruction in the spleen. They point out that the enlargement of the spleen may be a work-hypertrophy. Krumbhaar believes that the specific hormone of the spleen is activated by passage through the liver and by a series of interesting experiments he throws some light on the relation of the spleen to the blood and to the liver. He shows that there is a certain amount of anemia after splenectomy and that ligation of the splenic vein does not cause necrosis. This latter observation has a bearing on the changes in the spleen incident to thrombosis of the splenic vein. Singular difficulties confront the surgeon in experimental work in his attempts to solve these problems. Not the least of these difficulties is the fact that the experimentation on animals is on the normal spleen.

Relation of the Spleen to the Liver.

The liver is the great organ of defense. Its extreme importance is shown in the fact that it is one of the few organs which has the power of regeneration. We know that the liver destroys bacteria and protozoa and detoxicates poisons, both biological and chemical, which are brought to it from the portal circulation. The liver bears the most important relations to bodily metabolism, especially to the formation of sugars from carbohydrates and the development of amino acids from proteins. It receives through the portal vein all the nutritive material derived from food through the gastromesenteric system and also the nutritive values in the material which the spleen obtains from the blood.

The diseases of the liver are little understood and while a vast amount of work has been done, the nature of its metabolic activities is to some extent a matter of conjecture. Among its most important diseases are those which result from the intrahepatic development of connective tissue causing cirrhosis, a process which may be wide-spread or localized. The cirrhotic liver may be and is enlarged more often than we are led to think because of our more complete understanding of the alcoholic cirrhosis of the Laennec type, the so-called hob-nail or gin liver. Yet there is no fundamental difference between the atrophic cirrhosis and the hypertrophic cirrhosis of the beer drinker in which

fatty tissue smoothes out the connective tissue contractions and increases bulk. The cirrhosis secondary to splenic disease, if portal, is of the atrophic or hob-nail type, showing that the cause concerns protein, not fat metabolism. In biliary cirrhosis on the contrary, the liver is always enlarged. Three types of hepatic cirrhosis stand out prominently,—the toxic, represented by the alcoholic portal cirrhosis; the protozoal, of which syphilitic cirrhosis is representative, and the bacterial, of which biliary cirrhosis from common-duct infections is a type. In the portal cirrhosis the connective tissue is related to the portal venous system and ascites is an early manifestation while jaundice is a late one. In biliary cirrhosis the connective tissue is associated with the biliary canals, jaundice is an early manifestation and ascites a late one. Biliary cirrhosis is even less well understood than the portal type and there are various subdivisions such as the pigmentary (hemochromatosis) and the so-called Hanot's cirrhosis; the latter designation evidently includes cases of hemolytic icterus and serves only still further to confuse the issue.

Nature, in dealing with poisonous substances within the body in a general way, employs two methods: (1) detoxication and elimination, and (2) encapsulation. Portal cirrhosis may be looked on as failure to detoxicate and eliminate certain diffuse poisons and eventually there is an attempt at encapsulation of the noxious agents, resulting in the introduction of connective tissue about the portal radicals. The enlargement of the spleen, which so often accompanies portal cirrhosis, suggests that the primary source of these poisons may be in the spleen, and in some cases of portal cirrhosis in which we have removed the enlarged spleen, the results justify the presumption. In Banti's syndrome the portal cirrhosis is a late stage of splenic anemia and even in advanced disease the removal of the spleen often cures, the liver regenerating to a marked degree. In portal cirrhosis supposed to be primary, the spleen may be enlarged to a considerable extent without being manifest until a late stage. Sometimes it is a moot question whether the liver or the spleen was first affected,—all going to show how little we know about the whole subject.

The biliary cirrhoses, in many cases at least, have their origin in infections in the common duct, associated with gallstone disease. In such cases the spleen may or may not show great enlargement. In other cases in which no such infection exists in the common duct, the spleen may be found to be very large and suggests the possibility that it has carried to the liver toxic materials which have safely passed through the portal side but have exercised a large influence on the hepatic cells and the smaller bile ducts. This we know to be the fact in connection with hemolytic icterus, as the removal of the spleen promptly relieves the jaundice. The enlarged liver thus may not be a true biliary cirrhosis, as we had thought, but possibly in part at least an excess of function causing hepatic hypertrophy as well as cirrhosis in the attempt to care for the erythrocytic debris destroyed in the spleen and carried to the liver by the portal vein.

Relation of the Spleen to Bacteria and Protozoa.

Not infrequently living organisms are introduced into the human economy, and such introduction initiates bodily resistance. Vaughan has pointed out that a patient has typhoid during the prodromal period but that which we call typhoid is nature's defense manifestation. Preventive serums, such as vaccination for smallpox, typhoid, etc., act to educate the cells of the body to resistance. It is probably true that at times organs such as the tonsils which permit bacteria to enter the blood stream are acting as immunizing agents, allowing the early introduction of a few bacteria which act to cure rather than to cause the disease. Phagocytes may be considered educated defense cells ready to engulf bacteria on contact and perhaps depend on bacteria for their nourishment. In typhoid fever the spleen becomes enlarged as a result of its straining function. The accumulated bacteria which have been strained out of the blood are sent to the liver for destruction. A failure in elimination of the bacteria from the spleen to the liver may result in multiple or single abscesses containing pure culture of typhoid bacillus. We have operated in several such cases.

Enlargements of the spleen from chronic sepsis are not uncommon and may act as secondary distributing centers of infections. Focal infections in various parts of the body may act as the primary source of the bacterial invasion. Septic endocarditis is a notable example. In 8 cases we have removed a very large spleen showing the picture of sepsis—infarcts, etc. This type of chronic splenomegaly is most apt to be confused with splenic anemia.

While tuberculosis of the spleen is considered by some observers as never primary, this condition has occasionally constituted the only known focus in the body, and the removal of such a tuberculous spleen has permanently cured the patient. We have removed the enlarged spleen in 3 instances for tuberculosis supposed to be primary in the spleen. One patient died within the year from tuberculosis and we must conclude that there were other undiscovered foci. The remaining two patients have recovered and remain well.

Pathogenic protozoa, such as the plasmodium of malaria, the spirochete of syphilis, etc., produce chronic splenic enlargements from which it may be extremely difficult to dislodge the organisms. Jonnesco and others have removed the spleen for the ague cake of malaria, but with a high mortality. Newer and better methods of quinine therapy render so radical an operation unnecessary—at least very seldom indicated.

Spirochetal hibernation in the spleen is not unusual, and failure to eradicate the disease by salvarsan and prolonged mercurial treatment may result in a syphilitic spleen which permits not only luetic reinfection of the body but also causes a high grade of chronic anemia. In four cases of this type, removal of the spleen has promptly cured the anemia, and the lues has thereafter quickly responded to renewed treatment. In all of these spleens either spirochetes were found or gummata in spleen or liver were demonstrated, showing again the relation of the spleen to hepatic disease.

A very interesting question comes up in this connection. Must all the blood of the body pass haphazard through the spleen in order that these various materials, bacterial, protozoal, cellular and toxic, shall be strained out, or is there a definite

affinity in the spleen which furnishes an attraction for such elements? Rosenow's splendid experiments showing the specificity of bacteria and their definite attraction for certain organs, make it seem probable that some form of chemotaxis attracts to the spleen all of these various agents.

The foregoing brief résumé gives prominence to certain data which tend to establish that:

1. Enlargements of the spleen, not due to new growths, are associated with definite pathologic changes in the blood and the liver.

2. The enlargement of the spleen is often the result of agencies which are not primarily connected with the spleen, and in many cases the splenomegalia is a work-hypertrophy, a secondary, not a primary, cause of the disease with which it is connected.

For the purposes of this paper I have reviewed with some care the results of splenectomy for the relief of certain conditions with the idea of establishing the value of the operation. Dr. H. Z. Giffin, who has taken the utmost interest in this work, concerning which he has made a number of clinical contributions, has aided me in the review.

Pernicious Anemia.

We have removed the spleen fifty times for pernicious anemia. In each case the diagnosis was well established, and the spleen, with four exceptions, was above normal in weight. In some instances the spleen was greatly enlarged, weighing up to 2330 grams.

There has been no definite relation between the size of the spleen and the seriousness of the disease, nor was there any direct relationship between the result of the splenectomy and the size of the spleen removed. This of itself is a suspicious circumstance. The benefit derived from splenectomy, generally speaking, has followed the removal of a definitely enlarged spleen. The failure to establish such relationship in pernicious anemia, or to connect with the disease such gross and microscopic changes as are to be found in the removed spleens, would lead us to expect only limited benefit rather than cure of pernicious anemia through splenectomy. There was temporary improvement in every case, but following splenectomy we had some cases in which the cord changes progressed in spite of a great improvement in the anemia. We have not had a patient who has been cured, but all in all, in about 75 per cent. of the cases the benefit might be said to be sufficient to justify the operation. In the total number of operations three patients in our early experience died from the operation; the hemoglobin was under 30 per cent., the red cells were under a million. These patients should have been transfused before operation. Since practising transfusion in advance of splenectomy, when the blood has been seriously deteriorated, we have had no deaths. There were no operative deaths in the last 32 cases. In many cases after initial improvement by transfusion and splenectomy, relapse has taken place, followed again by improvement after transfusion. We have carried some of these patients along for months in fair health by repeated transfusions; as many as thirty have been given to a single patient. Following each transfusion there would be marked benefit, with gradual depreciation, until transfusion again became necessary. It has been believed that the introduction of new blood stimulates the hematopoietic organs, and this is probably the true hypothesis in patients whose bone marrow is not too severely damaged. Yet it should be noted that immediately after the transfusion, in certain cases, the anemia is relieved, the hemoglobin brought up from 10 to 30 points, and the red cells advanced appreciably, only to be followed by a gradual decline. These are the predominately myelotoxic types. It is an interesting conjecture whether or not the patient may live on the work of transfused blood as well as be stimulated to the formation of new blood. A probable explanation is that the life of the red corpuscles is much longer than we have thought, and that the anemia returns in proportion as this fresh aid is used up. The significant blood changes in pernicious anemia that differentiate it from secondary anemias are the changes in the number and type of the red corpuscles and in the blast cells found in the blood. The blast cells are the mothers of the erythrocytes, and each blast cell thrown into the blood represents a permanent loss of blood-making power. Therefore, neither stimulation nor treatment can reproduce that which has been lost. The difficulty with the whole subject of pernicious anemia concerns the fact that we do not recognize the disease until such vital and permanent changes as are indicated in the actual loss of these blast cells have taken place. It is even possible that pernicious anemia, in its beginning, is not a definite entity, but that it is a terminal change of several conditions which we have not recognized until they have reached the final stage. Clinically, however, it is a very definite disease when both history and blood picture are developed. Pernicious anemia may be called a cancer of the red cells, recognized in the hopeless stage. When the early histories of patients with pernicious anemia are studied the symptomatology seems fairly clear; yet many patients are seen with anemias which are suspected to be pernicious but which never develop the true characteristics of the disease. If pernicious anemia is to be cured it must be done before permanent damage to the hematopoietic organs has taken place. It is possible that certain types may be cured; yet so firmly fixed is our belief concerning the incurability of the disease that should we have patients cured by splenectomy we would be inclined to lift them out of the category of pernicious anemia and to group them with either hemolytic icterus or splenic anemia.

To sum up, splenectomy has a field of usefulness in selected cases of pernicious anemia, especially in those showing a marked hemolysis by the Schneider duodenal test and evidence of slight bone marrow damage. The operation of removal of the spleen for pernicious anemia is not, as a rule, difficult. The spleen is only of moderate size, and not very adherent.

Leukemia.

If there has been any one condition believed to be non-surgical and incurable, it is splenomyelogenous leukemia. The theory has been that 95 per cent. at least of such patients operated on would die as a result of the operation, and that the 5 per cent.

who lived would not be benefited. Yet we have long known therapeutic agents (benzol, *x*-ray, etc.) which would reduce the size of the spleen and would also improve the condition of the blood; and as the size of the spleen became reduced such improvement might be expected. With the use of radium, which could be readily applied over the area of the spleen, a vast change came about in the therapeusis of splenomyelogenous leukemia. I do not know of any clinical experience that is more striking than the result which follows the application of radium over a huge leukemic spleen. Many times the spleen shrinks so greatly as to disappear below the left costal margin, the white blood corpuscles drop from hundreds of thousands to under 10,000. I have seen a leucopenia produced, the white cells dropping from 600,000 to 3,700 in five weeks. Accompanying this extraordinary reduction in the size of the spleen and reduction in the number of white cells an equally extraordinary improvement in the anemia takes place, and the patient is marvelously benefited. As the spleen gradually increases again in size the white cells increase, the red cells decrease, and the patient loses ground. It is well to eliminate all of our presumptions concerning this disease and pause for a moment in perspective. Reduce the size of the leukemic spleen, and synchronously the white cells go down, the red cells come up, and the patient improves. As the spleen enlarges, the whites come up, the reds come down, and the patient goes down. Have we in this, as in so many other instances, allowed tradition to hamper progress?

My first experience in splenectomy for myelogenous leukemia was with a patient who came to the clinic with a greatly enlarged spleen, a white count of between 200,000 and 300,000, and who gave a history of having had the disease for two years. There had been very great improvement under *x*-ray therapy; at one time the white cells were reduced by it to a point under 50,000, but, as regularly happens, the *x*-ray had finally lost its effect, and her condition when examined was worse than it had been at any former time. The patient herself was greatly impressed with the definite connection between the size of the spleen and her condition, and was anxious to have it removed. I removed the organ, and the patient made an excellent surgical recovery. Within ten days the white cell count had dropped to less than 50,000 and the patient is greatly improved now, more than one year following the splenectomy.

Based on this experience, we have in a number of instances reduced the size of the spleen with radium until the blood count approximated the normal, and then removed the spleen. We have found it inadvisable to force an extreme reduction of the leucocytes before splenectomy. If the general condition of the patient is good, a leucocyte count of 30,000 or less is satisfactory. All the patients, save two, have been markedly relieved. In the 19 cases there were no operative deaths. That these patients are cured I cannot believe, but the experience has been interesting and suggestive.

Here again we find ourselves in difficulties not dissimilar to those in connection with the etiology and clinical course of pernicious anemia. One patient in our earlier experience, I remember well, had been treated for leukemia during a period of five months in a large and well-known hospital, and in another for three months. We diagnosed the condition as splenic anemia. The spleen was removed, the patient promptly recovered, and has remained well now for more than five years. It is possible that we recognize leukemia as a disease only after it has reached the hopeless stage, a terminal condition of a much more common though unrecognized malady. It is questionable whether all the cases of splenomyelogenous leukemia advance to the point where they are recognized as leukemia. These are interesting problems which cannot now be answered. Leukemia may be called a cancer of the white blood, recognized in the hopeless stage. The leukemic spleen is not adherent, as a rule, and after reduction in size by radium is readily removed.

Hemolytic Icterus.

We have performed splenectomy 19 times for hemolytic icterus. The results have been astonishingly good. I do not know of an operation giving more gratifying results. The jaundice which the patient has had for perhaps years will be perceptibly less in forty-eight hours, and within four days will have quite disappeared. Sixty per cent. of these patients have complicating gallstones, apparently due to the greatly thickened bile, the result of pigments derived from the disintegrated erythrocytes. There are two types of hemolytic icterus, the familial or congenital type of Minkowski and the acquired type of Hayem and Widal. In the familial type several members of the same family may be affected, and possibly it may be found through several generations. As a rule, it is less serious than the acquired variety. Although never robust, many times those affected with familial hemolytic icterus will live out a normal life expectancy. The acquired type is much more serious, and ends, as a rule, in death from some intercurrent malady after years of chronic semi-invalidism.

The outstanding features of hemolytic icterus are the enlarged spleen, more or less enlarged liver, and chronic recurring jaundice, without gross obstruction in the bile ducts. Bile is always to be found in the stool. Inasmuch as a high percentage of these patients have complicating gallstones, they may have an increase of jaundice due to a secondary infection from gallstones, varying the syndrome and introducing diagnostic difficulties. These patients all show marked anemia, and usually crises more or less serious develop in which there is pain over the region of the liver and spleen, with malaise, some increase of temperature, and an increase of jaundice. Chauffard and Widal have pointed out the diagnostic phenomena of increased fragility of the erythrocyte, which is practically constant. Splenectomy, as a rule, is not difficult in these cases, for although the spleen may be quite large it is seldom adherent to a marked degree. There was but one operative death in our series. This patient was operated on during a crisis, and death probably would not have occurred had the operation been performed in the interval between crises.

Biliary Cirrhosis.

Hemolytic jaundice is often confused with certain types of non-infective biliary cirrhosis, and especially with the so-called Hanot's cirrhosis. We

have removed the spleen four times for biliary cirrhosis, which could not be properly classified as hemolytic jaundice. All the patients were above 30 years of age. Were it not for the age, the cases could be called Hanot's cirrhosis. The results in three were very satisfactory. The jaundice disappeared to a large extent, and the patients were able to return to work; but in all the liver remained large. The operation of splenectomy for biliary cirrhosis is somewhat troublesome and difficult, more so than in hemolytic icterus. In our cases the spleen was large and there were many adhesions. In two the liver was sufficiently large to interfere mechanically with the operation.

Splenic Anemia.

Osler was one of the first to describe splenic anemia, and his classical contributions, coming as they did at an early time, created a great and lasting interest in the condition. Splenic anemia is at least a clinical entity, but has been confused with many varieties of splenomegalias, syphilitic, septic, malarial, hemolytic, jaundice, pernicious anemia, etc. Little by little an irreducible minimum is being reached and a definite type established. The patients having large spleens develop a progressive anemia and cirrhosis of the liver as a terminal condition to which Banti's name has been given.

The course of splenic anemia is chronic. There may be intervals of years in which the patient enjoys a fair degree of health, but eventually it leads to a fatal issue, the debilitated patients succumbing to intercurrent disease.

Hemorrhages from the stomach are of frequent occurrence in splenic anemia and sometimes hemorrhage is the first symptom that may be noted. The hemorrhages are probably gastrotoxic in origin and while, as a rule, fatal hemorrhage does not result, frequent, recurring hemorrhages cause great debility. The gastric hemorrhage of splenic anemia is a symptom well worthy of attention. It is not different from that which occurs in connection with hepatic cirrhosis and it is altogether probable that many of the unexplained hemorrhages from the stomach in which no local lesion of the gastric mucosa is to be found, are a result of the toxic condition which precedes, accompanies, or is caused by splenic anemia and cirrhosis of the liver. Balfour, in a paper on the causes of gastric hemorrhage, calls special attention to the relationship of the spleen and liver to the bleeding. In gastric hemorrhage we must think of the spleen and the liver as causative factors just as in the differentiation of the causes of jaundice the spleen must be thought of as well as the liver. Warthin and others have found that many cases of splenic anemia show thrombosis of the splenic vein after death and they believe that the thrombosis is the cause of the splenic condition. In one of our patients who died the cause of death was found to be due to long-standing splenic and portal thrombosis. The final catastrophe was brought about by thrombosis of the superior mesenteric vein. It may be contended that splenomegaly associated with splenic, portal, or mesenteric thrombosis (one or all) would be better grouped with infectious splenomegaly (probably streptococcal) rather than with true splenic anemia.

The pseudoleukemia of infants described by von Jaksch is closely associated, if not identical with splenic anemia, but because of the hematopoietic variability of infancy is often accompanied by a high white cell count. Such cases are usually to be relieved by dietetic management, but the spleen has been removed with prompt and striking improvement. Balfour splenectomized a two and a half year old child presenting the complete picture of splenic anemia.

Splenic anemia is cured by splenectomy in a high percentage of cases and it should be performed before portal cirrhosis or thrombosis of the splenic vein occurs. The spleen is usually large and, as a rule, extremely adherent and the operation is more difficult and dangerous than in any of the various other diseases for which splenectomy is indicated. In 43 splenectomies for splenic anemia we have lost 4 patients.

Clinically, patients with enlargements of the spleen are to be seen in whom the enlargement is apparently not producing symptoms, but these cases should be looked on as incipient splenic anemia. Such causeless splenomegalias as I have had opportunity to observe have eventually led to marked secondary anemia, although perhaps for years showing little effect on the patient's health. I have seen no good and much harm come from chronic splenomegalia, and other things being equal, such spleens should be removed on general principles.

Portal Cirrhosis.

The portal cirrhosis of the liver which so frequently accompanies the later stages of splenic anemia have led us to remove the spleen in 5 cases of primary portal cirrhosis in which there was enlargement of the spleen. The results on the whole have been gratifying, although one patient died following the operation. The remaining four are in satisfactory condition. For those portal cirrhoses with enlarged spleen which occur especially in young adults without alcoholic history, splenectomy would appear to be indicated. As a matter of fact in cases of this description do we not classify as primary portal cirrhosis those in which the liver condition is discovered first? If the splenic enlargement is first observed we call it splenic anemia with portal cirrhosis.

The technique of splenectomy I will not dwell on. For those who are interested, I would refer to the article by Balfour, "The Technique of Splenectomy."

Grenade Thrower's Fracture.—While this term has not yet come into fixed usage it is evident from a report by Cottard that the act of throwing a grenade can cause fracture of the humerus by muscular contraction. Singular to relate the three cases reported did not occur in actual warfare among seasoned throwers, but were found among practising recruits at the rear. No victim showed any predisposition. One break was transverse and the other two helicoidal. These seem to have been due respectively to movements of flexion and movements of torsion. In the first type the accident occurred in a powerful subject, while in the second type, in which a "spiral" throw was attempted, the musculature was not well developed. The fractures were all subperiosteal with good prognosis for union.—*La Presse Médicale.*

THE FIELD OF NEUROLOGICAL SURGERY.*

By WILLIAM SHARPE, M.D.,

NEW YORK.

PROFESSOR OF NEUROLOGICAL SURGERY, NEW YORK POLYCLINIC HOSPITAL AND MEDICAL SCHOOL.

The field of neurological surgery has so broadened during the past fifteen years as the result of the pioneer work of Horsley, von Eiselsberg, and Krause, and in this country of Cushing, that a number of neurological conditions which were formerly considered hopeless are now amenable to improvement at least, and in some early cases even a cure may be expected. This advance has been due chiefly to earlier diagnosis, an improved surgical technique and surgical judgment, and to better team-work of the surgeon and the neurologist.

Earlier diagnosis of many intracranial conditions is now possible mainly as the result of the more general and intelligent use of the ophthalmoscope; it is now commonly recognized and appreciated that the condition of marked papilledema and "choked disks" is the end result of preexisting pressure signs observable in the fundus of the eye.[1] No longer is it necessary to wait until a measurable papilledema occurs before it can be definitely stated that an increase of the intracranial pressure is present; besides the early fundal signs ascertainable by an ophthalmoscopic examination, the most accurate and definite test of an increase of the intracranial pressure is the lumbar puncture using the spinal mercurial manometer; in this manner the ophthalmoscopic findings can be confirmed. Intracranial localization has been greatly facilitated by the most thorough neurological examinations, and yet in many cases the localizing signs are so obscured by the increased intracranial pressure that they can be easily overlooked and they may even be absent; the importance of examining these patients is obvious. No patient should be allowed to develop a secondary optic atrophy and its resulting blindness while an effort is being made to localize the condition—an unimportant consideration in many cases; an early cranial decompression will save the eyesight and frequently the lesion can be localized later. Roentgen-rays are of much assistance in the diagnosis of many cranial and spinal lesions; by this means, long-continued intracranial pressure signs may also be determined and frequently the site of the lesion indicated; a negative picture especially of the skull, however, means nothing and frequently the interpretation of apparently positive plates is most difficult and at times confusing. Naturally in cranial and spinal injuries, the value of the Roentgen-rays is very great, indeed, especially regarding accurate diagnosis, and yet the treatment of such conditions, particularly of brain injuries, depends upon the presence or not of an increased intracranial pressure, whether the skull itself is fractured or not; whereas in spinal injuries the chief concern is whether the spinal cord has been irreparably damaged or not—the spinal fracture being of little importance neurologically so far as the treatment is concerned, unless the vertebral dislocation is so great that the spinal cord has lost its continuity.

*Read at a meeting of the Clinical Society of the New York Polyclinic Hospital and Medical School, Oct. 1, 1917.

An improved surgical technique especially regarding the team-work of operator and assistants has been a large factor in lowering the mortality of neurological operations; not only is the rapid loss of blood avoided, the duration of the operation lessened and thereby the shock minimized, but the risk of infection is also proportionately diminished to a point practically nil. Naturally, intracranial operations should not be hurriedly done, but they can be quickly and at the same time smoothly and safely performed; there is surely no advantage to be obtained in prolonging the operation either on account of faulty technique or as a result of such a complicated technique that the final closure of the wound is delayed many minutes. It is rarely necessary for the team to consist of more than the operator, two assistants and a nurse; the anesthetist is a most important member and many disasters in cerebral surgery have been due to faulty anesthesia; Doctor Hunt's observations have resulted in his using a method that has proved most satisfactory during the past four years.

The third important factor in the progress of neurological surgery during the past decade has been due to a better understanding of the neurological condition at operation, both by the surgeon and the neurologist at his side. Formerly, the surgeon knew little if any neurology, and the neurologist knew little if any surgery; the result was poor teamwork and thus frequently the surgical judgment was not the best. Today the surgeon should have at least a practical knowledge of neurological principles—both anatomically and physiologically; naturally a training in neurological pathology is most essential. In this manner a number of mistakes in surgical judgment may be avoided; if the patient cannot be benefited, by no means make the condition worse by an operation.

One of the most important aids to an increased knowledge of neurological lesions, particularly of the brain and of the spinal cord, has been the observation of the living pathology at operation, and if death should occur, then the careful study of the tissue itself at autopsy. During the past three years, a permission for autopsy has been obtained before operation in each case of neurological surgery at the Polyclinic Hospital (both ward and private patients)—no operation being performed unless the permission is given in writing—so that if a death should occur, then we shall ascertain the cause of death, and also the accuracy of the diagnosis and the treatment for the benefit of future patients. Naturally, when an operation is advised, it is in the belief that the patient will not die, but if the patient should die, then it is absolutely essential for the benefit of other patients that we ascertain the cause of death in order that possible similar mistakes, at least, may be avoided. I know of no means so enlightening to the doctor regarding the accuracy of diagnosis, particularly of intracranial conditions, than the post-mortem examination; besides the benefit of such knowledge to one's future patients, there is a marked tendency for these examinations to make the doctor humble as to his real knowledge and to keep him in that mental attitude.

If neurological surgery consisted chiefly in the removal of brain tumors it would be indeed a most discouraging field of endeavor. As you know, almost 80 per cent. of tumors of the brain are malignant, and even though a surgically successful removal of the tumor is possible, yet the end results are the same—the pitiful condition of the patient is merely prolonged; the severe headaches however, and the impairment of vision are thus temporarily relieved and even prevented by an early operative removal of the tumor. No patient should be allowed to become impaired visually from the increased intracranial pressure due to the growth of an intracranial tumor merely because the tumor cannot be located. These patients all should have an early decompression to relieve this increased intracranial pressure so that the vision will be spared, and then if the tumor does locate itself later, a successful removal of the tumor may be possible and yet the patient is not blind; I wish to emphasize this point as it is most discouraging to operate upon these cases of brain tumor who have become blind.

Tumors of the spinal cord, on the contrary, are much more favorable in that there is less liability of their being malignant; they can be more accurately located and are much more accessible surgically. The operation of laminectomy has become much less formidable within the past few years so that an exploratory laminectomy of a suspected spinal cord tumor should always be advocated early in order to anticipate any permanent damage of a compression transverse myelitis. The frequency of dural tumors of the spinal cord is most hopeful.

The condition of brain abscess has always been a most grave one. It usually results from an otitis media with the subsequent involvement of the mastoid; the usual site is the contiguous temporosphenoidal lobe, and less frequently the adjacent cerebellar lobe. As lesions of the cerebellum can be much more accurately diagnosed than those of the temporosphenoidal lobe, therefore, if we can rule out a cerebellar abscess, then the site must be in the temporosphenoidal lobe—a comparatively silent area of the brain, especially the right lobe in right-handed patients. Formerly, the otologists in cases of suspected abscess of the temporosphenoidal lobe would puncture the dura in search of the abscess through the "dirty" infected field of the mastoid; as all operations for brain abscess are really exploratory procedures, it is distinctly unsurgical to open the clean subdural spaces and to puncture the cerebral cortex itself through an infected area; if the abscess is not located (and this frequently happens), then the patient runs the big risk of a resulting meningitis and thus the usual occurrence—the exitus of the patient. Besides, the cerebral cortex should not be punctured blindly with a knife or puncture needle unless the dura has been opened so that it can be clearly ascertained whether an underlying cortical vessel is present or not; many disasters from the resulting hemorrhage have frequently occurred from such procedures. It is much more rational surgically and a much better exposure is obtained to locate the abscess if the operative incision is made through the "clean" subtemporal area, just as in a subtemporal decompression—the vertical incision naturally being used; if the abscess is found, then it can be satisfactorily and safely drained through the lower angle of the incision at the base

of the skull; and if the abscess is not found, then at least a decompression has been performed so that the intracranial pressure is relieved until the abscess may locate itself clinically, and the great danger of a meningitis and infective meningo-encephalitis has been avoided. In my series of brain abscess cases there are a number of them which I am sure I should have missed surgically if I had not used the better exposure of the subtemporal route.

The condition of cerebral spastic paralysis occurring in children is a most interesting study. In 1843, Mr. Little, of London, in his first monograph upon this subject,[3] stated that these cases were due to a lack of development of the cerebral tissues and also to an earlier meningitis; he did mention however, that this condition apparently followed in some cases of difficult and prolonged labor with or without the use of instruments, and were undoubtedly, in his opinion, due to an intracranial hemorrhage; it is very interesting to note that in his second monograph[4] upon this subject nineteen years later, in 1862, he states that, in his opinion, three-fourths of these cases of cerebral spastic paralysis in children are due to hemorrhage. These observations have been confirmed recently by more modern methods of diagnosis; it was formerly believed that hemorrhage in these cases caused a primary destruction of brain tissues—therefore, no regeneration was possible and thus an operative procedure would be of no value in treating the condition. Within the last five years, I have had the opportunity of examining and treating personally almost 1,400 children having the condition of spastic paralysis.[5] By the more accurate methods of differentiating the ones due to hemorrhage from those hopeless cases due to a lack of development and to a former meningoencephalitis for which nothing really can be done, it is now possible to diagnose the ones due to hemorrhage from these two conditions by means of careful ophthalmoscopic examinations of the fundi of the eyes and by a measurement of the pressure of the cerebrospinal fluid at lumbar puncture by means of a spinal mercurial manometer; if the ophthalmoscope reveals the signs of a definite increase of the intracranial pressure and those observations are confirmed by the spinal mercurial manometer (the normal pressure of the cerebrospinal fluid being 5 to 9 mm.), then we have an increased intracranial pressure and if this pressure is relieved permanently by a subtemporal decompression and its modifications according to the condition of the underlying cortex as ascertained at operation, then a definite improvement results in these cases, both physically and mentally. In this ceries of almost 1,400 cases there was an increased intracranial pressure in about 20 per cent. of them, that is, in about one out of every five cases examined, and these are the ones and only the ones that can be benefited by any operative procedure; I have now operated upon 298 of these children with a mortality of 28 patients (that is, 9 + per cent.) and the results have been very encouraging; naturally, the younger the child, the better the prognosis—the first few days of life being the ideal time for the operation, although most of the children have been between four and six years of age; the oldest patient however, was 23 years of age and a slight improvement resulted. Naturally, a sufficient period of time has not yet elapsed for us to ascertain the ultimate condition of these patients following operation, but their improvement has been so uniform and continuous in the younger children and the pathology of the condition being a hemorrhage upon the cerebral cortex and not in the cortex itself (in only 16 cases was the hemorrhage in the cortex or beneath the cortex), so that both the physical and the mental impairments are merely the secondary results of the increased intracranial pressure due to this supracortical hemorrhage.

The condition of hydrocephalus has been a very interesting one in that it has now been ascertained that the type of internal hydrocephalus is comparatively infrequent and that the type of external hydrocephalus is the usual condition in these cases. They both result from an earlier meningitis (if we exclude those cases of internal hydrocephalus due to tumor formation at the base) and the condition is therefore, a diffuse one; if the ventricles are blocked by adhesions or exudate in the aqueduct of Sylvius or at the formamina of Majendie and Luschka, then an internal hydrocephalus occurs, but if no such blockage is present, yet we shall have produced an external hydrocephalus because the cerebrospinal fluid cannot escape from the cerebrospinal canal through the blocked stomata of exit in the cortical veins, sinuses and lymphatics. The methods used in the past and occasionally now advocated of connecting the ventricles with the subdural spaces by means of tubes through the corpus collosum are therefore of little or no value in the treatment of this condition; even though the lumen of the tube should remain patent (and it rarely does), and even if the condition is one of internal hydrocephalus (which is much more rare than that of external hydrocephalus), yet such an operative procedure will merely be changing the condition of internal hydrocephalus to one of external hydrocephalus and therefore little or no improvement can be expected. The method recently used for draining the ventricles in cases of internal hydrocephalus and of draining the subarachnoid and subdural spaces in cases of external hydrocephalus by means of linen strands is a much more rational procedure surgically than any of the methods used in the past and its results have been very satisfactory; in the last report of 41 cases the mortality has been only thirteen patients.[6]

The condition of brachial plexus injury causing the so-called brachial birth palsy is the result of trauma to the plexus due to an overstretching of its nerves by a forceful separation of the head from the shoulder at birth. Undoubtedly if the plexus has not been completely severed, then many patients recover from the temporary paralysis of the arm but in those children where the overstretching has been so severe and even to a point of a loss of continuity of the nerve fibers, then a permanent paralysis of more or less degree will result unless the scar tissue resulting from the hemorrhage in and about the plexus is removed and the ends of the torn nerves are anastamosed by an operation. If the arm is completely paralyzed at birth so that not even the upper arm or the fingers can be moved, then the ideal time for the operation is at one month

of age (no anesthesia being necessary); if, however, the fingers or the upper arm can be moved slightly at birth, then we should wait until three months of age, and if no marked improvement has occurred within this time, then the operation should be performed. In these children I usually have the mother bring the child to the hospital in the morning, operate upon it, and then have the child taken home in the afternoon. The operation is not a difficult one technically, and there has been no mortality in a series of 104 cases.[7] These patients should not be allowed to reach the age of six years and even older without an attempt being made to improve their condition by an operation; the best results have been obtained in children under one year of age.

In fractures of the spinal column, I feel that unless we can prove absolutely that there is a complete severance of the spinal cord or that the spinal cord has been irreparably contused, that we should give the patient the benefit of an exploratory laminectomy within a short time after the accident in order to remove any bony compression, hemorrhage or edema of the spinal cord, and thus increase the patient's chances of a greater ultimate recovery of function. So frequently in patients whom we consider to have suffered a complete severance of the spinal cord with complete loss of sensation and motion beneath the site of the injury, that after three months and even longer they begin to recover their sensation and also motion of the extremities formerly completely impaired; these patients are the ones upon whom an early laminectomy should have been performed and thus the ultimate improvement would have been much greater than can be obtained at this late date. The operation of laminectomy is no longer the formidable operation of the past and its use should be much more frequently advocated than at present; these patients are most pitiful ones —the end result, unless something can be done for them, being but a miserable existence of a few years.

The diagnosis and treatment of brain injuries has advanced most rapidly within the last few years. The clinical symptoms and signs are so varied and frequently so confusing in these patients that it is a most fascinating field; apparently in many cases the more extensive the fracture of the skull, the less seriously is the brain injured, and on the contrary, the most dangerous of brain injuries are frequently not even associated with a fracture of the skull. As is well known, the fracture in these cases (if we exclude depressed fractures of the vault which should always be elevated or removed) is possibly the most unimportant part to be considered in the treatment, whereas the presence of a marked increase of the intracranial pressure with or without a fracture of the skull should immediately cause the patient to be withdrawn from that large group of patients properly treated by the expectant palliative method, and the advisability of an early operative procedure to relieve the increased intracranial pressure should be considered.

During the three years 1913, 1914 and 1915,[8] I examined and treated personally 239 adult patients having acute brain injuries with or without a fracture of the skull; in only 79 of these 239 patients (that is, 34 per cent.) were there marked signs of an increased intracranial pressure, and therefore only these patients were operated upon to relieve this increased pressure, whereas the remaining 160 patients did not show definite signs of an increased intracranial pressure and were therefore treated by the expectant palliative methods of absolute quiet, ice helmet and catharsis; if in shock, then the routine treatment of shock. It is thus seen that only one-third of the patients having brain injuries with or without a fracture of the skull were operated upon, and approximately this same ratio has continued during the past year. It is this careful selection of patients not only in regard to the advisibility of an operation or not, and if indicated, then the type of cranial operation used, but of the greatest importance—the ideal time for performing the operation—these factors have made it possible to lower the mortality of fractures of the skull from the average of 50 per cent. of most hospitals to 30.7 per cent. at the Polyclinic Hospital, and if we exclude the moribund patients dying within three hours after admission to the hospital from shock, internal injuries and in many cases the fracture of the skull being but an accident in the patient's general condition, the mortality is lowered to only 19 per cent.

In the treatment of brain injuries with or without fractures of the skull, if the patient is allowed to develop definite paralysis, a lowered pulse-rate, Cheyne-Stokes respiration and pulse and that appalling group of extreme intracranial pressure signs, then I agree entirely with the opinion so commonly now held that these patients "get along" just as well without operation as with operation at this late stage—the mortality being 50 per cent. and over; but the patients with brain injuries should not be allowed to reach this dangerous stage of medullary compression due to the high intracranial pressure—it should be anticipated by the accurate diagnostic methods now known, and if a marked increase of intracranial pressure is ascertained, then an early relief of it should be advised, not only to save the life of the patient, but to lessen the posttraumatic conditions of changed personality either of the excitable or the depressed type, persistent headaches, early fatigue, occasionally epilepsy and that long train of posttraumatic conditions in brain injuries and due in the majority of cases to a prolonged increase of this intracranial pressure.

Besides the lowered pulse- and respiration-rate which are comparatively crude signs of intracranial pressure and if of the irregular Cheyne-Stokes type, then most late signs of extreme intracranial pressure with its resulting medullary compression, the two most valuable procedures for determining a definite increase of the intracranial pressure are the examinations of the fundi of the eyes with the ophthalmoscope and the measurement of the pressure of the cerebrospinal fluid at lumbar puncture by means of the spinal mercurial manometer.

Although it is rare for a measurable papilledema and "choked disks" to occur in these cases of traumatic intracranial lesions with or without a fracture of the skull, yet the earlier, and, therefore, milder degrees of an edema of the optic disks should be most carefully "watched for" with the

ophthalmoscope as being one of the accurate signs of the presence or not of a definite increase of the intracranial pressure; the ophthalmoscope and especially the direct method is a most valuable aid in the diagnosis of cranial lesions. Rarely do these fundal examinations reveal an increased intracranial pressure within six hours after the head injury; this is due to the presence of shock in these patients who later exhibit the marked signs of intracranial pressure; as head injuries are usually accompanied by shock of varying degrees, naturally in these cases the blood pressure is low so that even if a large intracranial vessel was torn, yet there could be only a comparatively small amount of hemorrhage because the resulting increased intracranial pressure would soon be greater than this lowered blood pressure of shock, and therefore the bleeding would cease; however, as the patient recovered from the conditions of extreme shock, then the blood pressure would rise, and now more bleeding could occur intracranially until the intracranial pressure would again equal the lowered blood pressure; finally, if the patient survived this condition of shock, then the blood pressure would be continuously greater than the intracranial pressure, so that this resulting increased intracranial pressure would produce its characteristic signs in the fundus of the eye—a dilatation of the retinal veins, and an edematous blurring of the nasal halves, and if still higher, then an edematous obscuration of the temporal halves of the optic disks; a measurable papilledema and "choked disks" occur in these cases only when the intracranial pressure is extreme, due to a large intracranial hemorrhage of slow formation, such as the extradural middle meningeal type—just as in brain tumors or when the ventricles are blocked producing an internal hydrocephalus; naturally, if the intracranial hemorrhage forms very rapidly and of large amount, the patient usually dies within a couple of hours, so that "choked disks" have very little time to be produced; again, the shock following head injuries usually lasts for about six hours in the patients who survive and therefore it is rare within these first six hours for the ophthalmoscope to reveal definite signs of an increased intracranial pressure; it may be also noted that the patients who do not survive the condition of shock—usually die within the first six hours. It is, therefore, of the greatest importance to recognize these early signs of increased intracranial pressure by repeated ophthalmoscopic examinations and to realize that these oedematous blurrings of the optic disks are more than being merely within physiological limits; it is true that in cases of myopia there is normally an obscuration of the disk outlines, but these patients can be excluded by the second and following test, which should always be performed.

The most accurate means now known for ascertaining the presence or absence of an increased intracranial pressure is the measurement of the cerebrospinal fluid at lumbar puncture by the spinal mercurial manometer. It is similar to a blood pressure apparatus, as safe as a lumbar puncture when properly performed, and by it the varying degrees of intracranial pressure can be carefully recorded. The normal pressure is 5-9 mm. of mercury, so that if a pressure higher than 15 mm. is obtained at lumbar puncture, then we know that the signs of intracranial pressure, as shown in the fundus of the eye, are confirmed. This method of estimating intracranial pressure is most important in the differentiation of the intracranial condition of spastic paralysis due to hemorrhage at birth from those other causes of the so-called Little's disease. In other intracranial conditions producing the extreme stages of papilledema and "choked disks," and even their end results of secondary optic atrophy as in neglected cases of brain tumor, naturally it is not necessary to confirm the ophthalmoscopic findings in order to make a diagnosis of an increased intracranial pressure. If, however, in these traumatic lesions of the brain, we must wait until a "choked disk" results from extreme intracranial pressure in order for us to state that the intracranial pressure is high, and if we must wait for the pulse-rate to descend to 60 and below and the respiration and pulse to assume the irregular Cheyne-Stokes character of medullary compression, then undoubtedly the mortality of these patients will be 50 per cent. and even higher. Patients should not be allowed to reach this dangerous stage of medullary compression—this stage should be anticipated—and it can be by repeated ophthalmoscopic examinations and the measurement of the pressure of the cerebrospinal fluid at lumbar puncture.

In selected cases of mild intracranial pressure due to trauma, very frequently the convalescence can be shortened, the headaches relieved and the general condition of the patient greatly improved by lumbar puncture, and if necessary, repeated lumbar punctures; not only will the edematous "wet" condition of the brain be drained in this way, but a prolongation of the increased pressure be avoided and therefore the definite danger of posttraumatic conditions, so common in these cases, be lessened. Naturally, this method is only applicable to mild selected cases and lumbar puncture should never be advocated as a means of drainage in patients having high intracranial pressure or in subtentorial lesions for fear of a consequent medullary compression in the foramen magnum.

We now come to the most important and the difficult question in the treatment of brain injuries with or without a fracture of the skull: "If an operation is advisable, when should it be performed?" This question can more easily be answered by stating the two periods when the operation should *not* be performed. Naturally, we must exclude the majority (about two-thirds) of fractures of the skull that do not have a definite increase of the intracranial pressure and therefore no operation is indicated. (The depressed fractures of the vault naturally should always be elevated or removed.)

The two periods in which an operation is distinctly contraindicated in cases of brain injury, are, first, the condition of severe shock in the very beginning, and secondary, the condition of medullary edema and collapse—the death knell of the patient. To advise a cranial operation upon a patient—no matter how badly the skull is fractured, nor how extensive the intracranial hemorrhage seems, and that patient is in the condition of severe shock with a pulse-rate of 120 and higher, then the operation at that period of shock takes away whatever chance

the patient may have of surviving the shock: the operation is but an added shock and merely hastens the exitus. No patient having a brain injury should be operated upon in this condition of shock; the mortality is most high and if a patient does recover from an operation in this period of extreme shock, then he recovers in spite of the operation. Cranial operations for brain injuries in this stage of shock were frequently performed in the past and most disastrously, and thus operations were almost discredited in the treatment of brain injuries. The natural reaction following these early operations in the period of severe shock was to wait until there could be no possible doubt that the patient was going to die, unless, as was thought, a cranial operation was performed; that is, the patient was permitted to reach the period of extreme medullary compression—a pulse-rate of 50 and below, irregular Cheyne-Stokes respiration and pulse and profound unconsciousness, before a cranial operation might be considered. This is a most dangerous stage for these patients to reach, and it is doubtful whether recovery can occur even with an operation at this period—the mortality being very high. But if the patient has struggled through this period of medullary compression, and finally reaches the stage of medullary oedema, when the pulse-rate begins to ascend quickly to 120 and higher, respirations become rapid and shallow—that is, the stage of medullary collapse, then we have the second period when no patient sould be operated upon—they all die—operation or no operation. I feel that if these two extremes can be avoided and the latter of these, medullary collapse, can certainly be anticipated in the operative treatment of brain injuries and their signs cannot be overlooked, that the rational treatment of brain injuries from an operative standpoint depends upon the presence or not of a definite increase of the intracranial pressure whether there is a fracture of the skull or not; in some of the most serious cases no fracture was present—either to be ascertained at operation in the operated cases, or at autopsy. The aid of the Roentgen rays is important in the treatment of these traumatic cases only in patients with doubtful depressed fractures of the vault, and in latent fractures of the skull, where the bump is so apparently trivial that the patient might not be so carefully examined and treated as the condition would warrant. On the contrary, no patient with high intracranial pressure should be obliged to wait "over night" or for a period of hours merely to secure a Roentgenogram of the skull; it is of no importance in the treatment of these acute intracranial lesions whether a fracture is present or not; if there is a high intracranial pressure as shown by the ophthalmoscopic examination and by the measurement of the pressure of the cerebrospinal fluid at lumbar puncture by the spinal mercurial manometer, then a cranial operation is indicated to relieve this increased intracranial pressure both by enlarging the intracranial cavity and by the drainage of possible hemorrhage and cerebrospinal fluid; it is not so much a question of removing the hemorrhage as it is of lessening the increased intracranial pressure—whether that pressure is due to hemorrhage or edema—the operative indication is the same; many cases of head injuries at autopsy have revealed no hemorrhage at all—merely a "wet" edematous swollen brain, but sufficient to cause medullary compression and the death of the patient.

If an operation is considered advisable to relieve the increased intracranial pressure, then the operation of choice is the subtemporal decompression and drainage; if there are no definite localizing signs of the intracranial lesion, then the decompression should always be performed on the right side in right-handed patients in order to lessen thereby any possible operative damage to the motor speech area of the left cerebral cortex; in these cases it is not so important to remove the hemorrhage as it is to offset its pressure effects. In cases of depressed fractures of the vault showing definite signs of a high intracranial pressure, it is better surgical judgment to precede the elevation of the depressed area of bone by a subtemporal decompression so that when the depressed bone is removed there will be little or no danger of the underlying cerebral cortex being damaged by its protrusion upward through the bony opening; as the subtemporal decompression exposes a comparatively silent area of the brain—a portion of the temporosphenoidal lobe—its protrusion and possible damage would not appear clinically, whereas a partial paralysis, impairment of sensation or of vision might occur, and frequently does result from operations performed over the more highly developed areas of the cerebral cortex. Besides, the subtemporal route provides not only an excellent exposure of the middle meningeal artery and that portion of the brain so frequently involved in fractures of the skull, but it affords drainage to the middle fossa of the skull—the chief intracranial cistern—at its lowest point at the base of the skull; again, the thinness of the squamous portion of the temporal bone makes the operation a less difficult one technically. The vertical incision (and not the obsolete curved incision) should be used not only to render the operative hemostasis more effective in that the trunk of the temporal artery is clamped at its lowest point at the very beginning of the operation and thus there is no bleeding from its branches, but this incision also permits the removal of the underlying squamous bone as far as is possible beneath the temporal muscle—and yet the attachment of the temporal muscle to the parietal crest is left intact so that a firm closure of its separated muscle fibres is assured; this is a most important point in cases of high intracranial pressure as in brain tumor, where a cerebral hernia or fungus might result from an imperfect closure of the temporal muscle. The insertion of silver and celluloid plates and other foreign bodies beneath the scalp is to be most strongly condemned.

If the intracranial pressure is so high that the cerebral cortex tends to protrude through the bony opening, it is frequently wiser in selected cases to perform a similar operation upon the opposite side of the head immediately after the first operation; I have been obliged to do this in only five per cent. of the patients; they are the ones having a swollen edematous brain—"water logged" as it were, where the drainage of blood and cerebrospinal fluid is slight and not sufficient to cause a marked decrease of the intracranial pressure; in some doubtful cases, it is better judgment to wait for one or two days and

even longer before the second operation is considered advisable. The rubber tissue drains are usually removed on the first or second day postoperative, and the hospital convalescence ordinarily requires at least two weeks. Naturally, these patients should not enter into their former active life for a period of three months and even longer; a too early return to the strain and stress of modern life predisposes them to many complaints—both subjective and objective; repeated examinations of the fundus of the eye and of the superficial and deep reflexes are here most important in estimating the physical normality of the patient.

The end results of patients having brain injuries with or without a fracture of the skull have been an interesting study. It has become quite a common belief that once a man has had a fracture of the skull and then recovers, he is never the same person again. In 1912, I examined the records of three of the large hospitals of New York City during the decade of 1900-1910; the mortality of fractures of the skull was 46 to 68 per cent.; the mortality of the patients operated upon was 87 per cent.—this high percentage due undoubtedly to the operation being postponed until the extreme stages of medullary compression and oedema, and also to the fact that the operation performed was the "turning down" of a bone flap—a much more formidable procedure than a decompression—and then the bone replaced so that even the benefits of a decompression were prevented; besides, in many cases, the dura was not opened, and as the dura is inelastic in adults, therefore no adequate relief of the pressure could possibly be obtained. Of the patients, however, who were finally discharged as "well" or "cured," I was able to trace only 34 per cent., but of these 34 per cent. of the total patients found 67 per cent. of them were still suffering from the effects of the injury—that is, two-thirds of them were not as well as before the injury; the chief complaints were persistent headache, a change of personality of the depressed or of the excitable type and thus emotionally unstable, early fatigue making any prolonged mental or physical effort impossible and thus the inability to work, lapses of memory, spells of dizziness and faintness, and even epileptiform seizures in a small percentage of them. In examining the hospital records of the patients having these posttraumatic conditions, it was most interesting to ascertain that these were the patients—and there were but few exceptions—who regained consciousness gradually after several days and remained in the hospital for a period of four weeks and longer, whose charts made frequent mention of the severe headache and a low pulse-rate of 60 and in some cases below 60—that is, the usual clinical signs of an increased intracranial pressure; an ophthalmoscopic examination had rarely been made. Many of these patients still showed the results of the increased intracranial pressure in their fundi and at lumbar puncture, and these were the ones upon whom a cranial decompression even at this late date of several years caused a marked improvement; the operative findings were always associated with a "wet" swollen edematous brain; many of the so-called posttraumatic neuroses are, in my opinion, frequently superimposed upon this definite organic basis as the result of the brain injury. The treatment, therefore, of brain injuries should not be limited merely to the recovery of the patient as far as life is concerned, but it should also be directed toward obtaining a normal individual—approximating as closely as possible the condition of the patient before the injury.

Besides these neurological conditions frequently benefited by operative procedures, there are still other ones in this field that can be only mentioned in the present paper. The excellent results obtained in those cases of persistent trifacial neuralgia which finally, after the failure of all medical efforts, have had the posterior root of the Gasserian ganglion severed, are possibly the most dramatic; the surgery of the peripheral nerves has also made a marked advance within the past few years and especially is this true of the operative treatment of facial paralysis; these operative procedures will be discussed in a later paper. Of the other neurological conditions amenable to surgical treatment, this work is still in the experimental stage.

OBSERVATIONS AND TECHNIQUE OF LUMBAR PUNCTURE IN SEVEN HUNDRED CASES.

By Y. C. LOTT, M.D.,

NEW YORK,

HOUSE RESIDENT, DEPARTMENT OF NEUROLOGICAL SURGERY, NEW YORK POLYCLINIC HOSPITAL AND MEDICAL SCHOOL.

THERE has been very little emphasis or importance given to the value of lumbar puncture as an aid in the diagnosis and the treatment of organic and functional conditions affecting the central nervous system.

Through the courtesy of Dr. William Sharpe, Professor of Neurological Surgery at the Polyclinic Hospital, I have during the past two years performed lumbar puncture upon nearly all of the patients admitted to his service, either for treatment or as an aid in diagnosis.

The technique used in adults is to have the patient lying on his side, thoroughly flexed, thighs and knees upon the abdomen, and head upon the chest; median line of head and spinal column being on a level. In children the same position is used except a nurse or an assistant holds the patient by passing one arm between the thighs, over the upper shoulder to the back of the neck, while the other hand flexes the head upon the chest; in this way the position can be

very easily kept. An imaginary straight line is drawn between the highest part of the crests of the ilia on both sides across the spinal column, through the interspace between the fourth and fifth lumbar vertebræ, the site of election for lumbar puncture. At this point in the cauda equina region the puncture is more easily performed and is less dangerous and painful to the patient. If the interspace between third and fourth, and especially between the second and third vertebræ is used, then there is danger of seriously injuring the spinal cord by either trauma or hemorrhage. If the space between the fifth lumbar and first sacral vertebræ is used, then there will usually be more pain, due to the sensory nerve roots being more easily injured, and consequently the sensation is referred to the lower extremities.

With the selected site rendered sterile (and the skin may be anesthetized), a needle is inserted through the skin where the lines bisect; after the skin is pierced and the landmarks are again ascertained, the needle is passed forward and upward at an angle of 5° to the center of the spinal column in adults, or directly forward at right angles to the center of the spinal column in children. When the cauda equina region is reached, which is easily ascertained by the sensation of piercing the dura and entering a cavity, or sometimes by tingling in the lower extremity, then the stylet of the needle is withdrawn and the cerebrospinal fluid is allowed to escape; if some blood should escape (the cerebrospinal fluid being normally colorless), then it will be due to the fact that the needle either was passed through the cavity or has encountered the veins on the side. Then the needle should be withdrawn and passed again to the center of the cavity, and when this is reached no blood should escape unless due to the previous trauma from poor technique. When the technique is properly carried out (and the skin anesthetized), there should be practically no pain—no more than is caused by a hypodermic injection. Such being the case, it is useless to subject the patient to the dangers of a general anesthetic, unless the patient is highly nervous and will not be kept quiet. In children who can be held, what little pain there is—and it only lasts a second or two—does not, I think, make it advisable to administer a general anesthetic. Neither do I think it advisable to use local anesthesia, except in so far as the skin is concerned; it is neither necessary nor without danger to anesthetize the deeper tissues. Pain will be produced only when the periosteum or dura is pierced. No anesthesia should be used on the dura or in the spinal cavity, for then complications are very liable to follow, particularly infection and useless trauma. Ordinarily there is practically no danger, excluding the possibility of infection, and very little or no pain except as outlined in the above procedure, the pain in the lower extremities being only transitory should it occur. The procedure as described above is more easily performed, especially in children, and more accurately than the method frequently used, when the needle is inserted to the side of the spinal column in the interspace between fourth and fifth lumbar vertebræ upward and inward toward the center of the spinal cavity. I have found this method better only in fleshy people whose intervertebral spaces are small and the spinous processes short and very hard to palpate. Should the cerebrospinal fluid fail to escape after the stylet is withdrawn, and one is certain that the needle is in the canal, then it is due either to a blockage of the lumen by a blood clot, or to the nerve roots obstructing the entrance, or there may be very little cerebrospinal fluid present, as may occur in purulent cerebrospinal meningitis. In such an instance one must be sure that the lumen is patent by turning over the needle and withdrawing slightly, or placing it a little deeper and then waiting a few seconds. There are cases in which the cerebrospinal fluid is diminished; especially is this true in children, due to lack of development of the central nervous system or to higher intramedullary cord tumors. The spinal manometer may not register over 1 or 2 mm. of mercury, or there may not be over 5 drops of cerebrospinal fluid to the minute escaping. It is very hard to conceive of an entire absence of cerebrospinal fluid unless due to mechanical causes. The spinal fluid is secreted by the choroid plexus, possibly a small amount by the meningeal endothelium, and has a definite function and circulation. I have more than once made a "dry tap," but in these cases I have then attempted a puncture at different intervals, and finally obtained the cerebrospinal fluid. I believe the so-called "dry tap" (no fluid) is due to faulty technique, unless the cerebrospinal fluid is very flocculent and will not flow as the result of an exudate or a tumor obstructing the spinal canal, and consequently there is no circulation of fluid in the cauda equinal region.

Lumbar puncture is the most valuable aid we have to-day in the diagnosis of the degree of intracranial pressure. By this method we can fairly accurately diagnose it by means of the mercurial spinal manometer much more closely than by estimating the flow of cerebrospinal fluid per minute. It is normally 5 to 8 mm. in adults or 20 to 40 drops per minute. In estimating the pressure this way, the patient must be perfectly quiet, no coughing, no struggling, no crying, median line of the head on a level with the spinal column, otherwise the least exertion of the patient will cause fluctuation in the reading. There are other methods by which intracranial pressure may be ascertained, though not as accurately, such as ophthalmoscopic examination of the fundus of the eye, *x*-ray examination of the cranium, dilatation of the veins of the scalp, base of nose and upper eyelids, diastasis of the cranial bones, exophthalmos, etc.

The value of this method is inestimable in diagnosis of intracranial hemorrhage either from trauma or apoplexy. In the former there will be pressure, and the fluid may or may not be bloody. When blood occurs in spinal fluid the same throughout it is positive of intradural hemorrhage. If the blood is extraneous, the spinal fluid color will change while being withdrawn. In apoplexy we are able to diagnose the kind of hemorrhage, either capsular, in which there is very little or no pressure and clear fluid, or cortical and ventricular, where the cerebrospinal fluid is under pressure and may be bloody. In the latter two we are able to render surgical aid and improve conditions heretofore regarded hopeless.

Spinal puncture is equally important in recognizing early syphilitic involvement of the central nervous system, by its laboratory examination for a Wassermann, cell count, globulin reaction, colloidal gold test, etc. The so-called hopeless cases to-day, viz., general paresis, tabes dorsalis, etc., can by this aid be diagnosed very early—even before much destruction of the tissues takes place and the disease may be checked before it is too late. Should we rely solely upon the serological examination of blood and clinical signs for the diagnosis of syphilis of the central nervous system, the disease would be well advanced; whereas we could diagnose and combat it much earlier by a careful laboratory examination of the cerebrospinal fluid, the changes in the fluid taking place much earlier than the clinical signs, which are a late manifestation.

In cases having acute intracranial pressure, much can be accomplished in a diagnostic or therapeutic way by frequently removing the fluid slowly until the pressure is normal; this is done for relief of intracranial pressure or for drainage, as in traumatic, septic, or infectious conditions of brain and cord. Frequent drainage of cerebrospinal fluid is therapeutically indicated in selected cases in acute wet edematous conditions of the brain resulting from intracranial hemorrhage, chorea, delirium tremens, uremic coma, convulsions in epilepsy, encephalomyelitis. Very often I have seen a marked improvement in the above conditions within a few hours; patients coming out of coma, stuporous conditions or delirium, and convulsions, spasticity and paralysis diminishing. I have seen petit mal attacks stop for three months where previous to the puncture they occurred daily. In every case in which the patient is unconscious or paralyzed and the definite cause is not known, a lumbar puncture should be performed as an aid in differential diagnosis. More cases of fractured skulls will be diagnosed which were heretofore overlooked, and surgical aid can be rendered before it is too late.

I wish to emphasize the importance of draining the cerebrospinal fluid in mild cases immediately following intradural hemorrhage when the patients are conscious, rational, and apparently in good condition. By merely draining the cerebrospinal fluid in these cases one will be able to tide the patient over the critical period and save him from surgical interference, which may be indicated later. It is very probable that a percentage of traumatic epileptics and neurotics to-day who have wet, edematous, swollen brains would have been cured or benefited had the mere relief of intracranial pressure been done by lumbar puncture during the stage of irritation and congestion immediately following the cranial injury.

There are few cases of brain tumor on record in which immediate death has followed a lumbar puncture by causing medullary compression and edema from a choked medulla in the foramen magnum. When this complication arises death may occur within a few hours. This complication is most liable to occur when the intracranial pressure is exceedingly high, or the patient is in profound shock, or there is a subtentorial tumor or hemorrhage, and the fluid is rapidly withdrawn and in large amount, which should never be done. In these cases the fluid should be withdrawn very slowly, not more than 10 drops to a minute or not at all. If at any time during the test the patient should develop headache, nausea or vomiting, vertigo, changes in respiration or circulation, etc., while the fluid is being withdrawn, then it should be stopped immediately and the patient placed in the extreme Trendelenburg position. Where there is very much pressure the fluid should be withdrawn slowly and the patient required to lie down 24 to 48 hours, otherwise headaches, nausea, vomiting, vertigo, and elevation of temperature may occur. This may occur because, from high intracranial pressure of long standing, the brain is edematous and has a diminished blood supply to the choroid plexus and brain tissue; by temporarily relieving the intracranial pressure, even to a small degree, the blood supply is increased, causing over-production of cerebrospinal fluid, and one soon finds the intracranial pressure higher than at first, hence the reaction follows; whereas, by keeping the patient in bed, head lowered, if necessary, the blood pressure to the cranium is diminished, and a smaller amount of cerebrospinal fluid is secreted. Should reactions occur very markedly within a few hours or days after the test is made, which showed very little evidence of intracranial pressure, and the patient has been quiet in bed, it might be suggestive of intracranial pressure though all other pressure signs were negative or practically so.

Therefore it would seem that the intensity and duration of these reactions are in direct proportion to the degree of intracranial pressure, *i.e.*, the higher the pressure the more marked the reaction.

We are able from the above statements to arrive at the following conclusions regarding the value and technique of lumbar punctures:

1. As an aid in diagnosis of the degree of intracranial pressure, or in the diagnosis of intracranial injury either extradural by pressure or intradural by pressure and bloody cerebrospinal fluid, no more than 5 c.c. should be removed for diagnostic purpose, which is amply sufficient.

2. As a therapeutic measure in drainage of cerebrospinal fluid to relieve pressure in selected acute cases and in infective conditions, the cerebrospinal fluid should always be removed very slowly while the patient is lying down, especially in cases of high intracranial pressure either above or below the tentorium.

3. Lumbar puncture is a safe procedure when properly performed.

4. It is therapeutically contraindicated in high intracranial pressure of long standing or patients in profound shock.

Dipsomania in a Soldier at the Front.—Chavigny relates the case of a soldier who exhibited a violent crisis of excitement and exaltation of mysterious nature. It was learned that whenever things went wrong and especially after indulgence—even mild—in alcohol, he had similar outbreaks. Witnesses stated that habitually he was sober and drank water only. He was of low intelligence and only with difficulty was it ascertained that when a certain impulse or obsession overcame him he would drink anything—wine if he could get it, if not soapsuds, gasoline, etc. The man was adjudged irresponsible as the drinking was the result, not the cause of his mental crises.—*La Presse Médicale.*

THE APPEARANCE OF THE FUNDUS OCULI IN CERTAIN INTRACRANIAL CONDITIONS.*

By J. A. KEARNEY, M.D.,

NEW YORK,

ADJUNCT PROFESSOR OF OPHTHALMOLOGY, NEW YORK POLYCLINIC MEDICAL SCHOOL AND HOSPITAL.

CHANGES in the fundus of the eye as seen by the direct method of ophthalmoscopic examination, are so generally constant in certain intracranial conditions, that this observation becomes a most important one in the study of this type of cases. If the vaginal space which surrounds the optic nerve as far as the globe, is in normal communication with the intermeningeal space of which it is a continuation, then any increase in the tension of the cerebrospinal fluid exerts a corresponding pressure upon the optic nerve sheath and its contents and at times is sufficient to retard the normal outflow of the lymphatic and venous currents from the eye. As a result of this pressure, edematous changes are noted quite early in the fundus oculi. Should lumbar puncture be done when the changes are observed, there will usually be found an increase in the tension of the cerebrospinal fluid recorded by the spinal mercurial manometer.

If increased intracranial pressure is present, the edematous changes in the fundus of the eye, referred to above, occur in the following order and manner. The upper and lower margins of the optic disc, near the site where the blood-vessels penetrate, are slightly obscured; next, the nasal or vascular half of the disc and its margins become blurred; after this, the temporal half of the disc and its margins become hazy, and following this, the edema of the entire disc increases, until its height is measurable with the ophthalmoscope, and when this measurement reaches 3 diopters, it is called a choked disc. A papilledema is any measurable elevation of an edema confined to the disc; a choked disk is a papilledema of 3 diopters or more. An inflammation of the nerve head (optic neuritis) should not be mistaken for a papilledema; in optic neuritis the nerve head is only slightly swollen, the exudation obscuring its surface and margins, and it is not confined to the disc, but extends to the surrounding retina as well and is more correctly termed neuroretinitis. Many theories have been advanced to explain the cause of choked disc; no doubt a combination of factors is at work, but the mechanical one seems to be most plausible.

We have experimental evidence to show that increased intracranial tension alone is sufficient to produce a papilledema, if this tension is kept up for a certain time. Choked disc has been observed in 80 per cent of the cases with brain tumor, and estimated with the ophthalmoscope, they measure from 3 to 10 diopters in elevation. The changes that usually occur in a choked disc are as follows; at first it is red and juicy in appearance, then densely opaque lines pass down its sides; later it assumes a mound shape, and its entire surface is densely opaque with linear hemorrhages in it, the veins are swollen and tortuous, and covered here and there with infiltrate. After this, the regressive stages begin, the mass becomes pale, degenerate changes occur, and at the end of the process is an atrophic nerve head.

Thirty-five cases of brain tumor in Dr. Sharpe's service were observed, and thirty-two operated upon in the past two and a half years. From the standpoint of vision, a decompression is advised before the edema becomes densely opaque, because when this appears, gross destructive changes have taken place in the nerve and the time is passed when good vision may be assured. By an ophthalmoscopic examination of the fundus of the eye, many of the brain tumor cases are diagnosed as such for the first time only when sent to a hospital, suffering from what is said to be an obscure neurological condition associated with a persistent headache. It is of great importance, therefore, that every patient who complains of uncontrollable persistent headaches should have a careful ophthalmoscopic examination made of the fundus of the eye; and it would be well worth while even if only occasionally there will be found the edematous changes that reveal an increase in the intracranial tension. In such an event, we may be able to detect these changes in brain tumor cases, sufficiently early, not only to prevent the loss of vision by directing a cranial decompression operation to be done, but perhaps save the life of the patient.

Intracranial hemorrhage at birth is responsible for 70 per cent. of the spastic type of paralysis in children and 20 per cent. of the resulting idiocy and feeblemindedness now existing; the most damaging factor in these cases is the increase in the pressure of the cerebrospinal fluid as the result of the presence of the hemorrhage. One of the earliest indications of the existence of increased intracranial tension is determined by an ophthalmoscopic examination of the fundus of the eye. There is usually seen in the fundi of infants' eyes shortly after birth, when an intracranial hemorrhage is present, a general edema blurring all retinal and disc details, or a mild edematous blurring of the nasal half of the disc, or rarely a measurable edema occupying the entire surface of the disc (papilledema). This observation is important because it indicates an increase in the pressure of the cerebrospinal fluid and lumbar puncture findings usually verify it.

When intracranial hemorrhage occurs, there is usually a history of difficult or instrumental delivery at birth and the consequent injury to the infant's cranium and its contents. If the obstetrician who suspects a brain injury in an infant after difficult delivery with or without instruments, would direct a careful ophthalmoscopic examination to be made of the fundus of the infant's eyes as soon as possible after birth, there may be found an occasional child that shows edematous changes indicative of an increase in the intracranial pressure as the result of the presence of the hemorrhage, and if this increased tension is verified by a lumbar puncture, then in selected cases a modified cranial decompression operation to remove the hemorrhage is indicated, and when done gives excellent results. One human may be saved the fate of a spastic child and of an imbecile in the event of such an operation.

At present, however, most of the cases we see are advanced ones, with marked spasticity and of the mentally impaired type. The eye-grounds in these

*Read at a meeting of the Clinical Society of the New York Polyclinic Hospital and Medical School, Oct. 1, 1917.

cases reveal regressive edematous changes; the entire fundus is slightly hazy and presents the appearance of particles of finely ground black pepper, shaken lightly upon it; the color without the disc is changed from the normal orange red to red; the temporal portion of the disc is paler than normal and its margins are plainly visible; there is an increased redness in the nasal portion and a blurring of its margins; the upper and lower margins are blurred also; the veins are distended slightly out of proportion to the caliber of the arteries, and the light streaks in the blood-vessels are either missing or barely visible. While the foregoing is the usual picture, there are some eyes that exhibit milder signs while others are even more marked. A few there are that show post neuritis signs, such as pallor of the entire disc, indistinct margins, light streaks of exudate along the vessel walls, with leveling of the physiological pit; some that show an unequal distribution of retinal pigment, and others an entire loss of pigment.

Almost 1400 children having spastic paralysis with or without mental impairment, of ages varying from one day to twenty years, have been examined with the ophthalmoscope to ascertain the presence or absence of an increased intracranial pressure due to hemorrhage, and of this number 300 children have shown the distinct edematous changes above described—that is about one child in five examined. Naturally, having an increased intracranial pressure, these children are the only ones that can be benefited by any cranial operation.

In cases of recent fracture of the skull, and especially basal fractures, an increase in the intracranial tension is usually the most damaging factor. While it is interesting to know the nature and extent of the fracture revealed by roentgenograms, it is not so important from the standpoint of immediate treatment as the determination of an increased intracranial pressure. In three of the cases of the series studied, roentgenoscopy revealed a distinct fracture of the base of the skull, with no signs or symptoms developing, other than those following an ordinary concussion. Some of the cases of basal fractures in which an extensive hemorrhage occurred from the ear at the time of injury (virtually a "natural" decompression) displayed none of the signs or symptoms of an increased intracranial pressure. Observations were made in 212 cases, diagnosed as fracture of the skull in Prof. William Sharpe's service at the New York Polyclinic.

When recent cases were examined for the first time—that is within 24 hours after admission to the hospital, there is usually found a general edema blurring equally all the details in the fundus of the eye, and this blurring may be slight or sufficient to obscure greatly the usual landmarks. The venous twigs when visible are dilated out of proportion to the size of the accompanying arteries.

Frequent and careful observations are made while these patients are in bed. In cases uncomplicated by an increase in the intracranial tension, the retinal edema gradually subsides. Occasionally, in some of the routine examinations, after the first 24 hours following the accident, we note an increase in the general edema that previously existed, or to the edema that heretofore blurred equally all details, there is a decided added obscuration of the nasal half of the disc and its margins. These observations are most valuable, because they indicate quite early a rise in the intracranial pressure and the spinal mercurial manometer will confirm it at lumbar puncture in the majority of cases. Infrequently, there is an edema occupying the entire disc, the height of which is measurable with the ophthalmoscope (papilledema) even to the degree of "choked disc." In all these cases, the cerebrospinal fluid was found to be under higher tension than normal.

The degree of tension recorded at lumbar puncture in a given case and its pressure effect upon the cerebral cortex, are prime factors to be taken into account in deciding the kind of treatment necessary. Dr. Sharpe advises all cases of fracture of the skull to be placed at complete rest in bed absolute quiet, ice helmet to the head, and free catharsis maintained; if no signs or symptoms referable to an increase in the pressure of the cerebrospinal fluid develop, the above treatment is all that is given, but if the intracranial tension is increased up to nearly double the normal, then in selected cases repeated lumbar punctures are done, depending upon the nature of the symptoms. If, however, the tension of the cerebrospinal fluid is found to be double the normal or even more at lumbar puncture, whether or not the pulse rate is lowered, he advises a simple decompression operation to be done before a possible collapse of the medulla occurs.

At present a careful ophthalmoscopic examination of the fundus oculi is an important part of a complete neurological examination; it very frequently corroborates other findings and at times reveals changes that indicate neurological and other conditions that are impossible to determine in any other way. The diagnosis of many obscure neurological conditions is made possible only by the ophthalmoscopic findings.

Only selected operative cases of cerebral spastic paralysis, mentally impaired children, and fracture of the skull are reviewed in this paper, and it is only in these cases showing an increase in the intracranial pressure that an operation can offer any hope. The others naturally are not operated upon, as no improvement would result.

Because in the majority of cases it reveals changes quite early that indicate an increase in the intracranial tension, we attach great importance to a careful ophthalmoscopic examination of the fundus of the eye.

127 West Fifty-eighth Street.

PERNICIOUS ANEMIA.*

By JOHN F. JENKINS, M.D.,

OPELIKA, ALA.

It has been wisely said that pernicious anemia is a difficult subject. This is necessarily so because of two conditions: (1) the obscurity of the cause or causes of the disease, and (2) the disagreement among hematologists as to what permits of a diagnosis of pernicious anemia with the criteria at present available. It is better for the peace of mind of the student or physician to believe with Naegeli, that a diagnosis can be made on the blood findings

*Read at the annual meeting of the Chattahoochee Valley Medical and Surgical Association, held at Warm Springs, Ga., July 10-12, 1917.

alone—the embryonal type of erythropoiesis (megalocytes, megaloblasts, predominating if only a few nucleated red cells are present), the high color index, leucopenia with a relative lymphocytosis, the blood platelet diminution—this is a picture striking enough to make the diagnosis of Addison's type of anemia to any one who can remember these essential points. Dr. Mix puts it as laws and numbers and gives them as follows: The first law is that the color index is above unity; the second law is that there is an increase in the megalocytes, red cells larger than normal; the third law is that there is a reduction of the polymorphonuclears and a relative increase of the lymphocytes, a leucopenia with a relative lymphocytosis.

Besides these three laws, which are essential for the diagnosis, he gives two others. The fourth law may not be constant; it relates to the nucleated red cells—the normoblasts and the megaloblasts; and upon this, the fourth law, are based two types or rather grades of pernicious anemia, the ordinary and the aplastic types. In the ordinary type the blood-making organs make desperate efforts to replace the blood destruction and the cells of embryonal type are thrown into the circulation, sometimes in showers—the so-called blood crises, in which nucleated cells, the megaloblasts, always predominate over the normoblasts. This is the fourth law. But in the aplastic type these nucleated cells do not appear, and so the fourth law is nonoperative in this later type.

The fifth law is poikilocytosis—irregular and bizarre shapes of red cells.

Then Mix sums it up as follows: (1) Color index above unity; (2) Increase in megalocytes; (3) A leucopenia with relative lymphocytosis; (4) The relative preponderance of the large over the small nucleated red cells, in the ordinary type; (5) Poikilocytosis.

Now, for the man who does blood work it is very easy to make a diagnosis with these five rules to guide him, and a diagnosis is made and our patient is given an unfavorable prognosis. Unfortunately for our self-complacency, but fortunately for the lives of our patients, here come other hematologists who present case after case with the so-called blood picture of pernicious anemia, in which they have found the causes and treated them successfully, and their patients have recovered or else have enjoyed an indefinite period of good health. Grawitz and also Krehl claim that the so-called blood picture of pernicious anemia may be exhibited in syphilis, infection with *Bothriocephalus latus*, in the puerperium, and in a variety of other conditions, such as carcinoma of the stomach, gastric ulcer, hepatic affections, chronic losses of blood, diseases of bone-marrow, etc. They regard the blood picture of pernicious anemia as evidence only of an especially stormy regeneration of erythrocytes, which, because of the inadequacy of normal sources of new red cells, assume the type observed in the embryo.

So, even in this disease, which is essentially a disease for laboratory aid, it might be well to follow Murphy's dictum—that diagnoses should be made in cerebro and in the laboratory.

Cabot assembled 1200 cases—300 in his own practice—and, excluding all in which the causes were discoverable, finds the following clinical aids: Anemias of high grade, extreme weakness, peculiar lemon color of skin, sclera pearly white; 84 per cent. of the cases present lesions in the spinal cord and resemble spastic paraplegia, tabes, or peripheral neuritis. The symptoms of cord lesions may appear before a definite blood picture has developed. It occurs twice as frequently in females as in males, and most often between the ages of 30 and 60. It is a disease of frequent remissions. The subcutaneous fat is usually well preserved. Psychic changes are observed in some cases.

Postmortem findings are as follows: Fatty degeneration of heart, kidneys, and liver; increased deposits of iron in liver, spleen, and kidneys; the bone-marrow is red and shows active regeneration in the plastic type, but the reverse in the aplastic form.

It would take us too far afield to go into the discussion of the various classifications of anemias and we shall endeavor to limit ourselves to the discussion of diseases presenting the clinical and laboratory findings of pernicious anemia.

There are a number of conditions classed as aleucemic which present the symptomatology and blood picture of pernicious anemia, but there is an addition—numerous granular mononuclear leucocytes, which mark them as in the class of leucemias.

The anemia due to infection with *Bothryocephalus latus* is of especial interest, not only because it presents a hematological picture indistinguishable from that of pernicious anemia, but because it is unquestionably curable if the cause be removed before too great damage has been done. Repeated examination of the stools for the ova would exclude not only the bothryocephalus but other harmful parasites. And a point right here that needs emphasis—we rely very much on the findings of eosinophiles in all parasitic diseases of the intestines, but it must be borne in mind that as the anemia progresses the eosinophiles disappear and the blood assumes the embryonal type. The following fish tapeworm case, taken from Cabot's "Differential Diagnosis," Vol. II, illustrates this point:

Man, age 30, Finlander; red cells 1,000,000, Hb., 40 per cent., color index, 2; lymphocytes, 6,000; no achromia, many large sized red cells and poikilocytes; blood-plates decreased; 3 normoblasts and 4 megaloblasts seen while making a count of 200 lymphocytes. Has general physical weakness, but feels well while in bed; has good appetite; has no pain; has lost only a few pounds in weight. A diagnosis of pernicious anemia was made by the house officer, but was questioned by Dr. Cabot on the ground that not one case in a hundred of pernicious anemia is seen in a young man, and because of the prevalence of the fish tapeworm in Finlanders. Examination of the stool showed the ova of tapeworm, and under appropriate treatment the case went to complete recovery.

Again it should be remembered that there are certain blood poisons elaborated in the mechanical arts and the munition shops, that produce a picture of pernicious anemia.

There is a very striking condition, carcinoma of the bone-marrow, that produces a picture of the blood crises of pernicious anemia. Our differentiation would depend on two points: in carcinoma of the bone-marrow the flooding of the circulation with nucleated red cells is continuous and the normoblasts predominate over the megaloblasts, whereas in pernicious anemia these blood crises occur only

occasionally or not at all, and when they do occur the megaloblasts predominate. A clinical point would be that carcinoma of the bone-marrow is probably always secondary to carcinoma in one of four organs, the thyroid, the lymphnodes, the prostate, and the adrenals.

From the clinical side Cabot says that it is well to recall that cases of pernicious anemia may come to us in many strange disguises. They may appear without any complaint suggesting anemia and with merely a paralysis of the legs. Another type may appear with fever as a presenting symptom, so that a diagnosis of typhoid is often first made. Others begin with diarrhea and the anemia is wrongly attributed to the diarrhea, whereas the diarrhea ought to be attributed to the blood pathology. The majority of all cases, however, are distinguished by the fact that they present themselves complaining of one symptom only—weakness, a weakness unparalleled in any other disease, because it is not associated with pain, loss of weight, or functional disturbances, such as invariably accompany any other disease producing a similar degree of prostration.

This differentiation could go on indefinitely, depending upon the industry of the writer to search out case records and apply them as examples, but I will close with syphilis and mention that there may be an analogy between pernicious anemia and tabes dorsalis. Some years ago it was asserted that syphilis and tabes were frequently associated, then that 90 per cent. of the cases of tabes were due to syphilis, and now that tabes means syphilis. Authors are now claiming that 20 to 80 per cent. of cases of pernicious anemia present cord symptoms similar to those in the syphilitic and parasyphilitic spinal cord diseases, and that the treatment most successful in pernicious anemia and syphilis is the arsenical, and especially intravenous injections of neosalvarsan.

Treatment.—This may be summarized as in general, rest, sunshine, fresh air, easily assimilated and highly nutritious diet, blood transfusions or intramuscular injections. For the latter the citrated blood method is probably the most satisfactory and the easiest to use for the non-surgical practitioner. Then we must search for the cause and institute its appropriate treatment. Finally where a cause is not found or where syphilis is suspected, arsenic, as previously mentioned, should be used.

NEW SURGICAL TREATMENT OF ATROPHIC RHINITIS

By EDWIN A. GRIFFIN, M.D.,

BROOKLYN, NEW YORK.

CHIEF AND ATTENDING OTOLOGIST, RHINOLOGIST, AND LARYNGOLOGIST, SAMARITAN HOSPITAL AND BROOKLYN CITY DISPENSARY; RHINOLOGIST AND LARYNGOLOGIST, POLHEMUS CLINIC.

ATROPHIC rhinitis is a disease of the nasal cavities, resulting in destruction of the functionating properties of the mucous membrane. The causes are various in number, but when no special cause can be ascertained we call it idiopathic.

In these idiopathic cases, after all ordinary methods have been employed, such as tonics, vaccines, local applications, douching, change of climate, etc., and we have failed to obtain any improvement, what are we to do?

There is nothing so discouraging as to see the same face over and over again, and to hear the same complaints. Some rhinologists divorce themselves from these cases with dignity by referring them to one of their beloved friends or enemies. In desperation I endeavored to reconstruct the picture before me.

The surgeons can perform miracles in plastic beautification of the face, but the internal nose is no place to do any plastic work. The next best thing to do is to enlarge that which already exists.

A turbinectomy in a normal nose produces atrophic conditions, hence I began to enlarge the inferior turbinate. This I did in the following manner.

The nose is anesthetized in the usual way. The mucous membrane with its submucosa of the inferior turbinate is incised from the posterior tip to the anterior tip down to the bone. The membrane is now stripped downward and allowed to drop to the floor of the nose. The turbinate is then fractured toward the septum, by passing any flat long instrument, such as the ordinary blunt septal elevator, along the external surface of the bone.

The nasal cavity is then packed with strips of plain gauze saturated in albolene oil, being careful to pack both on the external and internal surface of the turbinate, as packing the nasal cavity internal to this bone would only push back the fractured fragments into place. The nose is then treated as after any surgical procedure.

In about seven weeks we have an entirely different looking turbinate. The triangular raw surface produced by the operation fills in with granulation tissue and the mucous membrane grows over this area. The growth of the membrane is aided by the hyperemia produced in the upper and lower segments of the turbinate by the incision.

This surgical technique is followed in the other nostril in about two or three weeks according to the convenience of the patient.

No astringents should be employed in the dressings. Silver nitrate in 5 per cent solution can be used for exuberant granulations.

This method may be employed in idiopathic atrophic rhinitis, or as a reconstructive method after destruction has already resulted from infection of the sinuses, especially the ethmoidal.

This operation is not a panacea for all atrophic cases and should not be resorted to until all evident causes for the atrophic condition have been removed.

I have followed this method in quite a few cases during the last two years with favorable results.

165 HANCOCK STREET.

Complete Pseudohermaphroditus Masculinus.—Moller relates that when a 49 year old single woman died of pneumonia and was autopsied the condition of the external genitals was as follows: cryptorchism and scrotal hypospadias with female type of hair on the mons, and markedly feminine configuration. Internal examination revealed uterus, vagina, and tubes, testicles and rudimentary epididymis and well developed ejaculatory ducts. A rudimentary prostate could be made out, but ovaries were absent. As for other evidences there was a beard, male breast and male voice. Pelvis and larynx were of male type. There were no changes in the adrenals.

Military Medicine.

THE EXAMINATION OF AN AVIATOR.

The medical examination of a candidate for the army flying corps is difficult because there is little precedent to go by. The flying man must be possessed of exceptional qualities both of mind and body, but the examiner must know as far as possible what these qualities are. A grave responsibility is placed upon the medical examiner, for if men are passed merely because they show no obvious symptoms of disease he may be guilty of their lives if they come to disaster, or if men are passed who cannot stand the strain he may imperil the fate of the country. As said before, however, very few medical examiners in the United States have had sufficient experience in the characteristics which constitute an efficient aviator, and until such experience has been gained they are perhaps right in erring on the side of severity in their examinations.

Capt. J. C. McWalter, attached to the British Royal Flying Corps, discusses in the *Medical Press* of Sept. 19, 1917, the essential attributes of the flying man. In a general way, he must be able to do well that which no animal has done before. He must be able to sustain, in the space of a few minutes, all the terrible alterations of altitude, temperature, pressure, moisture, and light which are experienced by one who suddenly soars 10,000 or 15,000 feet above the earth's surface. He must during every second of his flight have all his senses taut, and all he has ever learned of flying not merely locked up in his brain, but actually jumping forth at his finger tips. Not only must he be capable of the most intense and acute mental concentration on the problem of the task, but every muscle must be at the summit of responsive activity. Momentary forgetfulness, numbness, confusion, giddiness, lack of perfect coordination—any one of these simply spells death. To the gifts of the flying officer must be added most abundant resourcefulness and initiative if serious disaster is to be averted.

Of course, the man in possession of all these attributes, mainly mental, would make the ideal aviator, but the examiner cannot be expected to gauge all these and the most that can be expected of him is to know the physical disabilities that really disqualify, in other words to be able to distinguish between those that disqualify and those that do not. Also, he should be able to tell by examination and investigation if a candidate possesses the temperament and to some extent the mental attributes which go to make up the efficient flyer. Age is one of the most important points in the selection of a flyer. Youth is essential. "To stand the sudden and terrible strains involved in coming down from an elevation of 15,000 or 18,000 feet requires a beautifully youthful elasticity of nerve and muscle, of ligament, bone, and blood vessel."

According to McWalter, ear, nose, and throat troubles are those which most frequently deter men from qualifying as flyers. Tachycardia is very common after a flight, but not of serious importance. McWalter has found the acceleration of pulse after a short successful journey to be about 25 per cent. It may very quickly become normal again. The question of flying largely resolves itself into one of nerves, and the accurate examiner should be able to ascertain the type of man, or the type of abnormality or disease, which makes such a man so much the victim of his nerves that he may be gripped with fright, that he may not be able to coordinate his faculties to save himself from destruction. Temperament has much to do with this, and training can overcome such feelings in many instances, but McWalter holds that, as above noted, certain physical imperfections of the nose, throat, ears, Eustachian tube, and semicircular canals are most often the prime cause of the air fear that grips the man.

It is obvious that a medical man, in order to examine properly candidates for aviation, should have some practical experience in aviation—at least as a passenger in one or more flights. Undoubtedly, it is the most difficult form of examination which the army or navy surgeon is called upon to make, due, as we have said before, to the fact that one who has not himself experienced the trials of an airman can have but an imperfect idea of the qualities of body and mind which fit a man for this branch of the service.

The Scabies Problem on Active Service.—H. MacCormac and W. D. D. Small state that every man incapacitated from duty—it matters not by what means—is a gain to the enemy. From the point of view of the army, and of military efficiency, those diseases ought to rank highest in importance which cause most "casualties." Judged from this aspect, diseases of the skin occupy one of the premier positions, for under the conditions of trench warfare it is inevitable that they are to be met with in large numbers. The exact extent of the wastage for which they are responsible is known only to the authorities, but it is apparent to all that since many are contagious, successful efforts directed toward prevention and cure will amply repay by a very large gain of fighting men.

Of skin diseases found among soldiers—excluding pediculosis—scabies is by far the commonest. When uncomplicated, its effects incapacitate a man but little; but in consequence of the hard conditions of active service, secondary pyodermic conditions are frequent and severe, and these are a very real cause of prolonged sickness. In contrast to the three or four days required to complete a cure in an uncomplicated case these men have found that when pyodermic complications are established the period is greatly prolonged, the average stay in hospital over a large number of cases being 31.67 days. This figure does not include either treatment given elsewhere or the days spent in journeying to the base.

Scabies, as seen among soldiers, according to MacCormac and Small, differs in type from that usually met with in civil practice, and the difference must be appreciated in order to recognize the "carriers." The eruption is distributed in much the usual fashion, that is, on the wrists, hands, penis, lower abdomen, anterior axillary borders, elbows and buttocks. The characteristic interdigital burrows, however, are rarely seen. They were typically present in only 13 per cent. of their cases. Vesicles are much more common, though in many cases the hands are en-

tirely free from lesions of any sort. A correct diagnosis can only be made after inspection of the whole body. In the majority of cases the penis is involved, and the discovery of papules or crusts on either skin or mucous membrane is almost pathognomonic. This serves in doubtful cases to distinguish scabies from the acute pediculosis so frequently seen, and is, for this reason, an extremely useful diagnostic sign.

Secondary lesions may mask the primary disease. Most common is a variety in impetigo distributed in a characteristic manner on the lower buttocks, elbows and knees. The presence of pustules or crustings on one or all of these regions should at once suggest scabies, and lead to search for the more primary lesions elsewhere. Some degree of adenitis is the rule in all cases of scabies which have developed any form of coccal infection. The glands of the groin are those most frequently involved, and suppuration in this situation forms a not uncommon and troublesome complication. In the upper limb, severe lymphangitis with foci of suppuration seems to constitute the corresponding lesion. These septic foci usually occur in the upper third of the limb and on its inner aspect.

Dermatitis as a complication is most frequently the result of unsuitable, misapplied, or too long-continued treatment. Subjects of the seborrheic diathesis seem particularly liable to this complication.

Scabies must not only be distinguished from the pyodermic conditions, but also from pediculosis, pomphlyx, syphilis, and an unusual papular urticaria. This type of urticaria is not often seen in civil practice, and closely resembles scabies. Small red papules occur over the body generally, but particularly on the abdomen and anterior axillary folds. Wheals, or some degree of dermagraphia, may often be found or induced. Again, the wrists, hands, or penis are not involved, and the disease tends to disappear suddenly, while relapse is common.

With reference to the manner of infection with scabies, the evidence points to blankets as the chief means of disseminating the disease. Prevention, then, should include frequent disinfection of blankets by such a method as the Clayton sulphur vapor apparatus, or some other accepted form of sterilization. A few cases seem to have been contracted from horses. Great stress is laid by French writers upon the venereal origin of scabies, and this possible source should be kept in mind.

Of greatest importance is the early detection of every case of scabies. Each case undetected acts as a "carrier," and is the potential starting point of an epidemic. Frequent and thorough inspection of the individual soldier is the only means whereby early diagnosis can be assured. Infected men should be segregated and treated as speedily as possible, in order to prevent dissemination, and also to shorten the course of the disease, thus conserving man power. Curative measures should include exposure of the parasite and its ova, and their destruction by remedies, short of producing dermatitis. The subsequent disinfection of clothing and bedding must never be omitted.

Sulphur, it is generally acknowledged, is the most efficient remedy for treatment, and certainly, by reason of its curability and cheapness, it is that most suited for the extensive requirements of an army. It requires careful and intelligent application, and care must be taken that the patient receives neither too much nor too little treatment.

After a consideration of different methods of application of sulphur, such as the sulphur vapor method, MacCormac and Small consider that for simplicity and certainty no method is better suited for general use than that of simple inunction with sulphur ointment (B.P.), and admirable results will invariably follow *if the treatment is conscientiously carried out and with due regard to the necessary details*. The method of application is of paramount importance. They outline it as follows:

On first day, patient is given a hot bath and provided with plenty of soft soap and a large, moderately stiff nail brush. (a) Before entering the bath he is lathered all over with the soap, massaging it into the skin, paying particular attention to the special parts affected. This should be continued for at least ten minutes. (b) He then enters the bath, where he should be immersed to the neck. After steeping for fifteen minutes a thorough scrubbing with the nail brush follows. After the bath a final inspection is made, and any unruptured vesicles opened with a surgical needle. The object of this bath is to open up the haunts of the acarus and to expose it to the action of the parasiticide to follow. Shower or steam baths do not do this.

After removal of the soap, and drying, a liberal quantity of sulphur ointment (B.P.) is provided, with which the patient rubs himself vigorously all over, from the neck downward, special attention being paid to the vulnerable areas. When finished, he should be literally soaking in it. The inunction is to be repeated in this manner twice daily for three days, six applications in all. It is obvious that all clothing must be removed for the treatments.

Finally, on the fourth day, and not before, a second bath is given, and all of the patient's clothing and bedding sterilized to prevent reinfection. Everything, such as wrist straps, strings of identity discs, etc., should be included. The majority of cases where the treatment has been thoroughly carried out will be cured after three such days of treatment. Should any doubt exist, 2 per cent. betanaphthol in vaseline may be used daily for four more days. Only under exceptional circumstances should sulphur ointment be applied for more than three days, on account of danger of dermatitis following. At the completion of the treatment a certain amount of itching may be present; this is due to the remedy, and is not indicative of failure of cure; it will pass off, and should be disregarded. Some days will also probably elapse before all of the lesions have disappeared, although the man is no longer infective. A certain degree of pigmentation may persist indefinitely.

MacCormac and Small summarize their results as follows:

(1) Scabies in soldiers differs in type from the ordinary form seen in civil practice, particularly in the frequent absence of burrows or other lesions upon the hands, and in the great liability to pyodermic complications. (2) The primary disease is often masked by complications. In every case of impetigo, boils, dermatitis, or inguinal adenitis,

scabies must be carefully excluded before the diagnosis is considered complete. (3) Cases of scabies complicated by any of the above necessitate about ten times as long a period in hospital as simple cases; therefore, early diagnosis and treatment, before secondary diseases have become established, are of the greatest importance. (4) Regular medical inspection is essential for the detection of "carriers." Infected men should be segregated and treated at the earliest opportunity; horses may also require inspection. Blankets being the chief source of spread should be sterilized as often as possible. (5) Treatment by means of sulphur vapor is a method harmful often to the patient, and at all times dangerous to the community, in that it manufactures a class of scabies "carrier." In the interests of the army it should be discontinued. (6) The method of treatment most suitable to service conditions on account of efficiency, simplicity, and cheapness, is inunction with sulphur ointment, but this must be carried out in a methodical and thorough manner, and with careful attention to the necessary details. —*British Medical Journal*, Sept. 22, 1917.

The Work of the American Red Cross in France.—The American branch of the Red Cross Society has contributed generously and lavishly to the relief of European sufferers from the war. While immense sums have been given by the American public, the calls upon the Red Cross Society are so vast that further contributions will soon be required. It may be of interest briefly to recapitulate the general policies and the scope of the work on the Western Front.

According to a report to the American people published recently by the Red Cross War Council, the purposes of the general lines of activity in France are as follows: (1) To establish and maintain hospitals for soldiers in the American Army in France. (2) To establish and maintain canteens, rest houses, recreation huts, and other means of supplying American soldiers with such comforts and recreation as the army authorities may approve. (3) To establish and maintain in France canteens, rest houses, and other means of supplying comforts and recreation for the soldiers in the armies of our allies; (4) To distribute hospital equipment and supplies of all kinds to military hospitals for soldiers of the American or allied armies; (5) To engage in certain relief, such as (*a*) the care and education of destitute children; (*b*) the care of mutilated soldiers; (*c*) the care of sick and disabled soldiers; (*d*) relief work in the devastated areas of France and Belgium—furnishing to the inhabitants of these districts agricultural implements, household goods, clothing, and such temporary shelter as will enable them to return to their homes; (e) to providing relief for and guarding against the increase of tuberculosis; (6) to furnish relief for soldiers and civilians held as prisoners by the enemy, and to give assistance to such civilians as are returned to France from time to time from the parts of Belgium and of France held by the enemy. (7) To supply financial assistance to committees, societies or individuals allied with the American Red Cross and carrying on relief work in Europe.

Among the many activities at the Front with which the American Red Cross Society is concerning itself is that of medical research. There are extraordinary and abounding opportunities in France for the prosecution of such work. In the American units some of the ablest physicians and surgeons of the United States are serving and it is obvious that the supply of human material is practically unlimited. Investigations which may result in the discovery of means of treatment and modes of operation which would be of incalculable benefit to the human race are now in progress. However, in order to insure success or at any rate to carry on work under the most favorable conditions, special laboratory equipment and suitable buildings are needed. Facilities of this kind are, at present, greatly lacking nor can adequate assistance be obtained through ordinary government sources without delay, which places this source of supply out of the question. The Red Cross Society can afford the necessary financial aid at once, and by so doing will be helping the cause of humanity and science in the most practical way. In the prevention of tuberculosis in France, a country in which the disease is extremely prevalent, the Red Cross Society is doing its part. The American branch is cooperating with the Rockefeller Foundation in financing a commission for the prevention of tuberculosis, the Rockefeller Foundation paying administrative expenses. A Red Cross Infant Welfare unit has also been established in France. In fact, the Society gives assistance to all efforts tending to ameliorate the condition of soldiers and civilians in France who are suffering from the effects of ruthless warfare, and has immensely added to its reputation gained in previous wars.

Unit of Woman Doctors for France.—The Women's Hospital of New York has organized and completely equipped a unit of ten woman doctors for service in a base hospital in France. The unit had been organized under the direction of Dr. Rosalie Slaughter Morton and Dr. Elizabeth Johnson van Slyke, superintendent. The other members of the unit are: Dr. Dorothy Child and Dr. Florence Child, both Quakers, who were graduated in medicine from Johns Hopkins after attending Bryn Mawr; Dr. Ethel Lyon Hurd of Galveston, Tex.; Dr. Marion L. Stevens, a dentist; Dr. Nevins and Dr. Woodroffe of San Francisco; Dr. Esther Blair; Dr. de Lam Kinney of this city, a dentist; Dr. Esther Parker of Cornell. Miss Martha Townsend, graduate nurse, who has served for more than a year with the Fourth Contingent at Salonica and has the rank of Lieutenant in the Canadian Army, will accompany the unit. The unit will leave for France in the near future.

Medical Students to Have Military Training.—Students of the Medical College of Virginia have decided to organize for medical training. They are to wear uniforms and have a regular army officer to drill them. The second, third and fourth year students of this institution have been furloughed until actually needed.

Drafted Men Rated by Psychological Tests.—An announcement from Washington states that the psychological examination of recruits has a twofold object. Each man will be given a rating which will be used by the officers in command as a guide in selecting men for promotion and for special duties requiring more than the average

intelligence. The medical purpose which is considered the more important one is to find what men are so far below the average intelligence as to demand serious consideration for discharge or for assignment to manual labor under careful supervision. The aims of the examinations are to measure native intelligence and ability, not schooling, to disclose what a man can do with his head and his hands. These psychological examinations are being conducted at camps Devens, Dix, Lee, and Taylor.

Tuberculosis Among Drafted Men.—Dr. Louis I. Dublin, in speaking before the North Atlantic Tuberculosis Conference recently, made the statement that 2 per cent. of the men between the ages of 21 and 30 years called for draft examination have been found to be tuberculous. In the French Army 500,000 cases of active tuberculosis have been found, while the British soldiers have not suffered so greatly. This is attributed to the greater care exercised by the British in excluding cases of incipient tuberculoisis. In discussing this subject there was considerable criticism of the action of our draft boards in accepting men in incipient stages of tuberculosis.

Gift for British Red Cross.—"Our Day" collection in behalf of the British Red Cross is led by a collection of $1,000,000 from the American Red Cross. Of this amount $250,000 is for the relief and comfort of the sick and wounded in the hospitals and casualty clearing stations in the lines of communication where the British forces are fighting, $250,000 is for the maintenance of auxiliary hospitals and convalescent homes in England, and $500,000 is for institutions in Great Britain devoted to restorative work among disabled British soldiers.

Campaign Against Alcohol Among Soldiers and Sailors.—The United Committee on War Temperance Activities in the Army and Navy, which has been organized by eighteen leading national temperance organizations, has undertaken to educate the soldiers and sailors in the American Army and Navy regarding the evils of the drink habit. The work of the committee is to be done through the Knights of Columbus, the Y. M. C. A., and the Army and Navy Chaplains. A Soldiers' and Sailors' Manual is being prepared and also bright, snappy posters and literature. Stereomotorgraphs will be installed in each Y. M. C. A. "hut," and portable outfits will be furnished to smaller camps. The slides are all carefully prepared to drive home some fact regarding the effect of alcohol on the soldier, his army, and his country. Provision has also been made for a number of moving picture films which will be displayed at 500 or more military stations during the period of trainng.

Jesse H. Jones, a business man of Houston, Tex., has been appointed Director General of Military Relief of the American Red Cross to fill the place formerly held by John D. Ryan, whom President Wilson appointed to membership on the War Council. Mr. Jones will give his services to the Red Cross for the period of the war without compensation.

Dr. P. G. Hamlin of Richmond, Va., First Lieutenant, M.R.C., U.S.A., attached to the British forces in France, was wounded on October 5. The published report does not give the nature of the wound.

First Lieutenant A. Graham, an American in the Medical Reserve Corps attached to the British forces, has been severely wounded in the thighs by gunshot.

Cuban Red Cross Plans to Send Unit to France.—The Cuban Red Cross has begun the work of equipping a one hundred bed hospital unit, manned by Cuban physicians and nurses, for active service on the western front in France. A fund of $1,000,000 with which the enterprise is to be financed is being raised by Cuban women. A national Red Cross "tag day" to be observed in all parts of the Republic has been planned.

Astor Home for Convalescent Hospital.—The Army Medical Department has accepted Vincent Astor's offer of his country home, Ferncliffe, at Rhinecliff, to be used as a convalescent hospital for American soldiers wounded in the war. It is reported that several other owners of large estates have made similar offers, one of them being James Speyer, who has offered his country home at Scarsboro.

Infectious Diseases Eliminated from Navy.—Surgeon General Braisted in a recent report made to Secretary Daniels states that typhoid fever and other infectious diseases have practically been eliminated from the navy by modern preventive measures. Despite the enormous increase in the personnel of the navy since the beginning of the war fewer than ten cases of typhoid fever have been reported during this period. Practically the only diseases that give much concern are those of the respiratory type, principally mumps and measles. These are associated with a low mortality rate or none at all.

The Hun Attack on an American Hospital.—Further details of the attack on the American base hospital in France continue to come to light. It seems that Dr. George E. Brewer of New York was buried under debris from a shell, miraculously escaping serious injury. One of his nurses lost both eyes, and another one eye.

A Much Wounded Soldier.—A correspondent of the *Associated Press* reports that the most wounded soldier who has thus far been treated in a London Military Hospital is Lance Corporal A. T. Staines of the Canadian Mounted Rifles, who has been invalided home with 84 wounds, most of them from the explosion of a single rifle grenade.

Fire in Army Hospital.—The explosion of an oil stove started a fire in the receiving building of the base hospital at Camp Devens, Mass. The fire destroyed the one-story wooden building housing the receiving ward and the office of the hospital. The remaining thirteen buildings were unharmed. Two medical officers who were in the building were slightly burned.

The Demand for Artificial Limbs.—A representative of the American Association for Foreign Trade recently arrived in this country for the purpose of getting materials for the manufacture of artificial limbs. He reports that as a result of a conference of the missions of the Allies it has been decided to establish a factory for the manufacture of artificial limbs in Switzerland.

New York, October 27, 1917.

CONDEMNATION OF BIOPSY.

IN January of this year the Cancer Commission of Harvard University rather unwisely offered to supply the medical profession of Massachusetts the services of its laboratory for the free diagnosis of suspected cancer tissue. This was in accordance with the movement so unaccountably started by the American Society for the Control of Cancer, some members of which have time and again exposed the dangers of such a practice. The society seems to have acted solely on the recommendation of a committee consisting of three distinguished pathologists, without surgical experience, who made a report in favor of this procedure. The suggestion of the committee was most unfortunate, for, as might have been anticipated, it was ignorantly acted upon by a number of bodies composed of laboratory workers, internists, or others, whose very little surgical knowledge proved to be a most dangerous thing. Among these was the New York City Health Commissioner, who issued an invitation to the medical profession to bring to the department laboratory for diagnosis slices of suspicious tumors of the breast and other parts. The suggestion seemed so horrible that the MEDICAL RECORD at once cried out against it and warned its readers of the fearful danger to which they would expose their patients if they acted upon the Health Commissioner's urging, and we returned to the matter again and again at the risk of tiring our readers, for the thought of the certain death to which so many trusting women would be hastened unless the Commissioner withdrew his invitation would not be stilled.

Commissioner Emerson has not yet withdrawn his invitation; indeed, he recently published a report stating that 104 specimens were submitted to the laboratory up to July 1. "The majority of the specimens received," the Commissioner says, "have been tumors taken in part or in toto from various parts of the body and a diagnosis of malignancy has been made in a good number of cases where the diagnosis has been uncertain, prior to microscopic examination." It is heartrending to think of the fate of those victims from whom the tumors, afterward diagnosed as malignant, were taken "in part," for their speedy and painful death is as certain as anything can be in medicine.

Although, therefore, the MEDICAL RECORD has not yet succeeded in persuading the Commissioner to put an end to this destructive work, we are rejoiced to learn that our warning has led to an investigation resulting in a suggested modification of the "Procedure Recommended in the Diagnosis of Early and Suspected Cancer of Different Organs" published by the American Society for the Control of Cancer. Even the original scheme did not justify the New York Health Commissioner in his unqualified recommendation of biopsy, but the modified one absolutely condemns his action. This modification is proposed by Dr. Robert B. Greenough of Boston, who was moved by our protests to send a circular letter, asking for an expression of opinion on the justifiability of biopsy in certain specific cases, to all members of the American Surgical Association, the Clinical Surgical Society, the American Gynecological Association, and the American Association for Cancer Research, and to the directors of the American Society for the Control of Cancer. Replies were received from 134 of those addressed and the proposed modification of the practice is based upon the opinions expressed by an overwhelming majority of the answers. This will be found on page 749 in this issue. Briefly summarized, excision, followed by cauterization, of a portion of a suspected growth of the skin, lip, tongue, palate, tonsil, buccal mucous membrane, breast, rectum, bladder, or cervix uteri is permissible "only when facilities for immediate frozen section diagnosis are available and the operation for cancer if it prove necessary, can be completed under one anesthesia." Obviously frozen section diagnosis is the work of a hospital laboratory only and is not included in Commissioner Emerson's tragical proposition. "When we speak of free diagnosis of suspected cancer tissue," Dr. Greenough says, "we are speaking of the service which may be rendered by one or more central laboratories, involving the removal of tissue, placing it in tissue preservatives, sending it to the laboratory, and waiting for a certain length of time, say seven days, for a positive report. Under these conditions we must make up our minds when and where, if at all, the removal of fragments of tissue suspected to be malignant can be justified and recommended. One of the most widely accepted principles in the surgery of malignant disease is that cutting into cancer tissue leads to a spread of the disease. The proofs of the truth of this assertion are so common in the experience of every practising surgeon that examples are scarcely needed, but I may say that in my own experience not one case of cancer of the breast has been saved in which a primary local operation has been done under the erroneous diagnosis of a benign tumor, even when followed at an interval of seven to ten days by the most complete operation, when the pathological examination of the original tumor disclosed malignancy. With regard to other situations it is probable that the danger is not so great, but it is difficult to draw the line, and

eighteen Fellows of this Association [the American Surgical Association] in their replies stand squarely by the general proposition that exploratory incision into cancer tissue is *never* justified."

Dr. Greenough deserves great credit for this work undertaken at the cost of much time and trouble, and we commend the perusal of his article, published in the *Annals of Surgery* for October, 1917, to the Health Commissioner of this city. If, after reading and digesting it, he still urges indiscriminate biopsy, we can only say that his action can no longer be regarded simply as a deplorable error, but will come dangerously near to something of which the law can take cognizance.

THE TREATMENT OF FUNCTIONAL CONTRACTURE BY FATIGUE.

THREE years of intensive warfare have brought results in the development of military medicine, which, with reference to treatment and cure, have heavily taxed the ingenuity and skill of both the surgeon and medical man. Occupying a position doubly important among these conditions have been the functional war neuroses, because of the complexity in their basis and makeup, as expressed jointly by the subjective and objective symptoms. Their treatment has not only called for a thorough investigation of the physical side of the afflicted individual, but, what is even more important, the objective symptoms have called forth the employment of every possible curative measure for even temporary relief. It is acknowledged that one of the greatest and most striking difficulties encountered among the objective symptoms is that of muscular contracture. Every orthopedic surgeon who has had experience in the war can tell of the heretofore hopeless outlook which was all he had to offer to the victim of a muscular contracture due to functional neurosis.

Now, according to an article published in *The Lancet* for September 15, this outlook has improved. E. F. Reeve offers a method of treatment, which he has originated and developed, and from which he has obtained remarkable curative results. This method has been worked out on the theory that the conditions of functional neurosis are dependent, not so much upon the absence of a normal function as upon its exceedingly disordered activity. The principle of the treatment consists entirely in producing a condition of fatigue in the muscles responsible for the contracture. This is obtained by continuous passive movements in a direction opposed to the normal action of the contracted muscles. It can be understood that in many cases force must be exerted in the early stages of the treatment in order to overcome the offered resistance; but this gradually lessens, until, according to Reeve, a limp, toneless, and tired condition of the muscle or muscles is produced and they can no longer cause the deformity for which they were once responsible. Evidently by the time the muscles have regained their tonicity a normal balance of strength is established in all the surrounding muscles. The psychical side of the patient is called into play by the enlistment of his cooperation and assistance as well as that of other patients in the hospital, once similarly afflicted, but cured. This is effected by quietly and carefully explaining to the patient both the nature of a spasm and the reason for tiring out the contracted muscles.

Several cases, illustrative of the method, all of which had previously undergone other forms of treatment, are presented by Reeve. One of the most interesting is that of a man aged 29, who was wounded by a rifle bullet on June 24, 1915. The bullet entered through the intraspinous fossa of the right scapula and passed out through the pectoralis major just internal to the head of the humerus. The patient stated that he had been operated upon two months later in an attempt to join the nerves, and the wound became septic, necessitating a further operation. From August 15, 1915, the arm was flexed to the side and every attempt to move it evoked strong muscular spasm. The elbow was extended. For a long time the fingers were tightly flexed and the wrist extended, but this condition cleared up in March, 1917, only to recur the following May. In June of the same year, free movement was obtained by electrical massage, but the spasm returned within half an hour after treatment. The patient came under the care of Dr. Reeve on June 12, 1917. The arm was tightly held to the side. It could be forcibly abducted, but sprang back on being released. There was, however, free movement of the wrist and fingers. Treatment was begun three days after admission. At first the elbow was forcibly flexed and this operation was repeated for some hours until at last all trace of spasm had disappeared. The following day the arm, which was still freely movable at the elbow, was forcibly abducted and this movement was repeated again and again until, after some four or five hours, the limb could be held voluntarily away from the body. This forcible abduction of the limb from the body was repeated day after day, till at the end of the week, the patient was able to lift his hand to the back of his head, all trace of spasm having disappeared.

The several advantages of this mode of treatment are summed up by Reeve as follows: (1) No apparatus of any kind is required and no specialized knowledge on the part of the physician is necessary. (2) It is accessible to all, since the personal influence of the physician does not operate to the same extent as in treatment by purely suggestive methods. That such personal influence must come into play to some degree cannot be denied, for although the patient's cure is brought about in the first instance by a purely physical means, psychical factors must operate once fatigue has worn off. It is probable, however, that the all-important factor which conduces to the permanency of the cure is the actual demonstration to the patient that the contracture no longer exists, it having been dispersed by a

method which he has no difficulty in understanding. (3) It is applicable to cases which have been treated previously without success by other methods, and its success is not prejudiced by these previous failures. It therefore appears to be preferable to suggestive measures. (4) The process by which the contracture is actually eliminated is a physiological one and is not subject to interference from psychical factors—*e.g.* the degree of the patient's faith that he will be cured. (5) Any fear of a relapse is distinctly reduced by the patient's knowledge both of the mechanism by which the disability was produced and of that by which he was cured. (6) Such a method does not undermine the patient's self-respect in the slightest degree; in fact, in most cases it may increase it by deepening his self-knowledge and convincing him that his disability is a natural phenomenon and not something occult. The shortness of time required, as compared to other modes of treatment for this condition, offers a decided advantage in time of war.

ETIOLOGICAL FACTORS OF ACNE VULGARIS.

ACNE VULGARIS is one of the most frequent of the skin affections, perhaps the most common of all. Its etiology, however, is by no means clear; that is to say, that dermatologists have not made any particularly close investigations into the subject. One reason for this lack of attention is that the affection is not dangerous. But while it causes no physical suffering, and never endangers life, it occasions a great deal of physical discomfort and mental distress, so much so in some instances that it renders existence a burden. In the *American Journal of the Medical Sciences* for October, 1917, Dr. Albert Strickler relates his views as to the etiology of acne vulgaris gained from his own clinical experiences and those of others.

He first points out that in a study of its etiology one is impressed with the importance of gastrointestinal symptoms. Lloyd W. Ketron and John H. King have, within the past year, studied by means of the fluoroscope, by test meals, and by analyses of gastric contents, the condition of the digestive tract of those suffering from acne vulgaris. Thirty persons formed the material of this investigation, and it was shown that out of this number 93 per cent. exhibited some gastric abnormality while 70 per cent. manifested intestinal abnormality. The most common gastric findings were hyperacidity 48.1 per cent., retention 36.6 per cent., atony 33.3 per cent., and ptosis 40 per cent. The most common intestinal findings were cecal stasis 46.6 per cent., ptosis of the colon 36.6 per cent., and right lower quadrant adhesions 23.3 per cent. The gastrointestinal conditions were present in a marked degree in 60 per cent. of the cases studied, and in a minor degree in the remaining 33 per cent. These authors conclude that the well established clinical observation as to the association of abnormalities of the gastrointestinal tract with acne vulgaris has, in many cases, a well founded pathological basis.

Strickler has made investigations by himself and in conjunction with John A. Kolmer and Jay F. Schamberg with regard to the etiology of acne vulgaris and with respect to the relation between gastrointestinal conditions and the affection. His conclusions and those of his fellow workers are as follows: (1) Acne is due, in the vast majority of instances, to the acne bacillus. (2) This organism is probably normally present on the skin of individuals not subject to acne, but in those individuals who develop the disease the acne bacillus is activated by other factors. (3) These activating factors are in a certain percentage of cases either the colon bacillus or its toxins, or both, as shown by the complement fixation test, and in a lesser degree the staphylococcus of both bacteria acting in conjunction. (4) The rôle of the colon organism in acne is further substantiated by the indol experiments, which seem to indicate some variation in the behavior of the colon acne organism from that of the normal controls. These indol experiments are, of course, only suggestive. (5) It must be recognized that there are cases of acne due either to internal administration of certain remedies or to certain local applications. (6) An increase in the size of the thyroid gland was noticed in a certain percentage of acne patients. The exact significance of this fact cannot be definitely stated, though it should be remembered that some writers are of the belief that an increase in the size of this gland is an indication of intestinal toxemia. (7) It is the belief of the authors that the use of cosmetics plays a rôle in the increase of this affection. (8) From their studies they do not see any relation between food anaphylaxis and acne vulgaris. (9) Among other factors puberty plays an important predisposing rôle. (10) Furthermore seborrhea, anemia, derangement of the stomach, nervousness, and pelvic disease are of more or less etiological importance but never play the rôle of an exciting factor.

SEASON AS A FACTOR IN THE SPREAD OF POLIOMYELITIS.

THE season, or rather its attendant atmospheric conditions, in itself is not a cause of poliomyelitis, but the state of the weather may be concerned indirectly in the dissemination of this dangerous disease. It is a somewhat curious fact that while the consensus of authoritative opinion with regard to the spread of poliomyelitis is that it is by means of nose and throat secretions from individual to individual, climatic conditions are opposed to the theory. Diseases which are spread in this manner occur for the most part in cold weather. Poliomyelitis, however, has always exhibited a marked preference for warm weather, and as Professor Winslow has pointed out, this fact taken by itself would seem to show that either an insect or some intestinal factor plays a prominent part in the etiology of the disease. The epidemic of 1916 was

a conspicuous instance of the influence of season in the spread of the malady, as with the onset of cool weather its prevalence abated and in a short time it disappeared. In order to ascertain how far the principle of summer prevalence of poliomyelitis has held, T. G. Hall, writing in the *American Journal of Public Health* for October, 1917, has set down the results of his studies of the records of 52 epidemics which have been reported during the past seventy-five years in different parts of the world. He has shown by means of charts that, as a rule, the outbreaks have begun in the warmer months. The peak has usually occurred in August or September, with practically all the cases between the first of June and the last of November. Moreover, epidemics have occurred more frequently by far during dry seasons. Hull has demonstrated that 76 per cent. of the epidemics began in months when there was a deficiency of rainfall and the dry weather persisted throughout. Twenty-four per cent. of the epidemics began in months in which there was an excess of rainfall, but in no instance did the wet weather continue through the entire period of the epidemic. Again, the relation between the number of cases and the amount of dry weather is quite pronounced. Thus it appears to be decidedly more than a coincidence that poliomyelitis and dry weather go together, and this fact also lends weight to Winslow's suggestion that insects are largely concerned in the spread of poliomyelitis.

News of the Week.

New Hospital for Brooklyn.—The cornerstone of the new hospital in Auburn Place, Brooklyn, which is to replace the Cumberland Street Hospital, was laid recently by Mayor Mitchel and Controller Prendergast. The building will be thoroughly modern in construction and equipment and will cost about $800,000.

Christmas Red Cross Seals.—The National Association for the Study and Prevention of Tuberculosis announces that the Christmas seals will soon appear and that it hopes to sell $3,000,000 worth this year. Since these seals were first sold in 1908 the association has gained $5,000,000 from this source.

Anthrax at Bellevue Hospital.—A death from anthrax occurred recently in Bellevue Hospital. It is reported that of six cases of this malady cared for at Bellevue Hospital five have died and one has recovered.

Army Medical Supply Depot Looted.—During the week of October 15, five men were arrested on the charge of having stolen drugs and other medical supplies from the Army Medical Supply Depot in Greenwich Street. The thefts alleged to have been revealed during this week amount to over $7,000. The accused men were held in $7,500 bail.

New York Hospitals in Urgent Need.—The United Hospital Fund of New York, formerly the Hospital Saturday and Sunday Association, reports that as a result of the conditions created by the war 46 hospitals show a total deficit of $1,000,000. Estimates compiled by the Fund show that in 1917 the expenses of these 46 hospitals will be at least 10 per cent. greater than in 1916. Hospital expenses, it is stated, have increased more than 25 per cent. since the beginning of the war. In 1916 the expenses of these 46 hospitals were $6,862,359 and their total income only $6,371,832, leaving a deficit of nearly $500,000. For the year just ended there was a further deficit of $700,000, which will bring the deficit of the current fiscal year to more than $1,000,000. The New York Hospital reported a deficit of $96,812 for the year ending September 30; the German Hospital, $52,724; the Volunteer, $40,377; the Polyclinic, $21,430; Lying-in, $19,416. Full returns of the deficits have not been received from several of the large hospitals, but are said to exceed any in their history.

The Hebrew Orphan Asylum reports that during the past year 1,248 children have been cared for in the institution and 225 boarded out at a total cost of $400,000. The report states that the boarding out department has been especially successful.

Ambulance Wrecked in Accident.—An ambulance of the Norwegian Hospital, Brooklyn, was wrecked as a result of a collision with a trolley car at Forty-sixth Street and Fifth Avenue, Brooklyn, on October 14. The ambulance surgeon, Dr. John M. Tamraz, and the driver sustained lacerations and minor injuries.

Industrial Commission to Adjust Medical Claims.—A recent decision of Justice Benedict in the Appellate Division of the Supreme Court had led the Industrial Commission to adopt a new procedure on claims for medical compensation to injured employees. Heretofore the commission has been limited to determining the reasonableness of a doctor's bill, and if the bill were not paid a suit had to be brought to recover the amount. Justice Benedict's decision is held to establish in effect that no action can be maintained in the courts for medical services, but that the matter must be determined by the commission. Hereafter all the claims for medical services to an employee under the Workmen's Compensation law must be made direct to the commission which will pass upon the claims, make awards covering medical services in amounts that may be deemed reasonable, and issue an order directing payment which, if not obeyed, may be filed in the County Clerk's office and become a judgment of the Supreme Court. The award will be made against the employer or insurance carrier only when the employee has requested the employer to furnish medical services or has accepted the physician offered by the employer. If he provides his own medical attention he will be obliged to bear the expense and the doctor may have a lien on the compensation to be paid.

The Doctor's Part in Food Conservation.—Charles O'Brien, author of "Food Preparedness of the United States," suggests that the physicians of this country can aid Herbert Hoover in his task by rationing the nation in much the same manner as though the entire population were under medical treatment. He says that the doctors are about the only persons the American people will listen to when it comes to matters of diet. The doctor knows the heavy penalty of over-feeding and its train of ills. He is therefore in a unique

position to be a leader in food conservation. If individually and as a whole through their medical associations, the physicians would realize their opportunity and take every possible occasion to advise their patients to reduce their food intake, the saving in the aggregate would be tremendous. The writer quotes Dr. M. Hindhede of Copenhagen as saying that the death rate among German men before the war was 18.2 a thousand per annum, and that this was attributable to the fact that in the preceding fifty years the German had become the world's champion meat eater. Dr. Hindhede believes that a lower percentage of protein and fewer calories than prescribed by the old standards are sufficient. As further evidence in support of his position he states that the death rate of Berlin had fallen to 12 per thousand last fall, that London under the mere restriction of high prices has achieved a like result, and that in Belgium under the efficient management of the Relief Commission the astonishingly low death rate of 8 per thousand was attained.

Harvey Society Lectures.—The first of the series of Harvey Society lectures for 1917-18 will be given at the New York Academy of Medicine on Saturday evening, October 27, 1917, at 8.30 P.M., by Prof. W. T. Porter of Harvard. Subject, "Shock; Observations at the Front."

Dr. Bulkley's Lectures on Diseases of the Skin.—The Governors of the New York Skin and Cancer Hospital announce that Dr. L. Duncan Bulkley, assisted by the attending staff, will give the nineteenth series of clinical lectures on "Diseases of the Skin" in the out-patient hall of the hospital on Wednesday afternoons, beginning November 7, 1917, at 4.15 o'clock. The lectures will be free to the medical profession, on the presentation of their professional cards.

Census Weekly Health Index.—As a health index the Bureau of the Census will publish each week mortality reports from the largest cities in the United States. There will be given for each city the total number of deaths reported, the death rate, the number of deaths under 1 year of age, and the proportion of infant deaths to total deaths. Where the data are obtainable for the previous five years, averages for the corresponding weeks will be given for each city.

Dr. George H. Kirby has been appointed director of the Psychiatric Institute on Ward's Island, New York City, by the State Hospital Commission. He has also been appointed Professor of Psychiatry at the Cornell University Medical College, to succeed Dr. August Hoch, who has resigned and will remove to California.

The State Medical Society of Wisconsin at its annual meeting, held in Milwaukee, on Oct. 4 and 5, elected the following officers: *President*, Dr. George Windesheim of Kenosha; *First Vice-President*, Dr. Oscar Lotz of Milwaukee; *Second Vice-President*, Dr. T. W. Nuzum of Janesville; *Third Vice-President*, Dr. Carl Dodge of Marshfield; *Secretary*, Dr. Rock Sleyster of Waupun; *Treasurer*, Dr. S. S. Hall of Ripon. *Delegate to the American Medical Association*, Dr. C. H. Lemon of Milwaukee; *Alternate*, Dr. Wilson Cunningham of Platteville.

The West Virginia State Medical Association at its fiftieth annual meeting in Fairmont, on Oct. 5, elected the following officers: *President*, Dr. H. R. Holrooyd of Athens; *First Vice-President*, Dr. Charles O'Grady of Charleston; *Second Vice-President*, Dr. W. J. Judy of Belleville; *Third Vice-President*, Dr. D. W. Waddell of Fairmont; *Secretary*, Dr. Howard J. Anderson of Marytown; *Treasurer*, Dr. H. C. Nicholson of Charleston. *Delegate to the American Medical Association*, Dr. F. LeMoyne Hupp of Wheeling. *Editor of the Journal*, Dr. J. R. Bloss of Huntington.

Obituary Notes.—Dr. ROBERT WATTS, who had been in active practice in New York City until within a year, died, on Oct. 15, at the age of 80 years. He was a graduate of the College of Physicians and Surgeons, New York, in 1861, Surgeon of the One-hundred and Thirty-third New York Regiment during the Civil War, consulting gynecologist to Roosevelt Hospital, and consulting physician to the City and St. Mary's Children's Hospitals.

Dr. E. M. STEWART, a graduate of the University of Louisville, Kentucky, died at the home of his parents in St. Joseph, Mo., at the age of 33 years. He was at one time assistant surgeon in the United States Public Health Service and later had charge of the Atchison, Topeka and Santa Fe Hospital at La Junta, Col.

Dr. JAMES A. B. SIKES, a graduate of the Atlanta Medical College, in 1876, died at his home in Bainbridge, Ga., September 30, aged 65 years.

Dr. HENRY JULIUS COHEN, a graduate of Cornell Medical College, in 1909, died in the Methodist Hospital, Brooklyn, N. Y., after an operation for appendicitis, on Oct. 18, aged 29 years.

Dr. MAY DARRACH, formerly of New York City, died of pneumonia at Atlantic City, on Oct. 18. She was a graduate of the Women's Medical College of the New York Infirmary for Women and Children, in 1904, and founder of the Darrach Home for Crippled Children in New York City and a home for crippled children in Newark, N. Y.

Dr. HARRIET SCUDDER MASON, a graduate of the Eclectic Medical College, New York, and formerly house physician of the Little Mothers' Aid Association, Manhattan, died at her home near Rochester, N. Y., recently.

Dr. EMMETT BURR DALEY, for many years a practicing physician of Bennington, Vt., died in the Samaritan Hospital at Troy, N. Y., on Oct. 10, aged 62 years. He was a graduate of New York University Medical School in 1879.

Dr. THOMAS R. RUSSELL, probably the oldest practising physician in the State of Wisconsin, died suddenly at his home in Oshkosh, on Oct. 5, at the age of 90 years. He was a graduate of the Vermont Medical College, in 1852, and Surgeon of the First Wisconsin Cavalry during the Civil War.

Dr. LEANDER J. CROOKER of Augusta, Me., a graduate of Dartmouth Medical College in 1869, died of cancer of the stomach on Oct. 9, aged 69 years.

Dr. WILLIAM MOORE WRIGHT, a graduate of the Washington University Medical Department, St. Louis, in 1869, died at his home in Huntingdon, Tenn., on Oct. 7, aged 79 years. He was a surgeon in the Confederate Army during the Civil War and later superintendent of prisons for Tennessee, a trustee of the Tennessee Hospital for the Insane, near Nashville, and a trustee of the West Tennessee Hospital for the Insane.

Correspondence.

A WORD ABOUT OSTEOPATHY AS I HAVE OBSERVED IT.

To the Editor of The Medical Record:

Sir:—During the past summer I have had occasion to see in consultation several patients to whom I advised a trial of osteopathy, after diagnosis and treatment from not a few of our best medical men had been tried and proved unsuccessful. My strong impression, upon thoughtful consideration of what I have seen and read, is that in connection with our different hospitals it is desirable that osteopathy should be recognized as a valuable adjunct in some cases to our other means of treatment, medical or surgical. In this special form of treatment, as in all others, the physician of all-around knowledge should be the final counselor and adviser. He it is who by his wisdom and wide experience should control, and not the enthusiast of too exclusive theories or practice. So it is, or should be, in regard to every one-sided view in medicine or surgery. Already I have known many theories and practices come and go, and where there was almost absolute faith a great scepticism, equally wrong and foolish, sprang up, and, alas, remained during several years, or until a sane and level-headed appreciation of facts served to counteract former errors.

No doubt osteopathy, properly practised and controlled, is able to help in many instances a suffering or disabled body. Of course, it should be understood that equally with every system of special practice in medicine or surgery it should not be indorsed unless the practitioner has shown by previous education and training that he has a right to advise or treat men or women whose bodies, or even minds, require helpful doing.

The great drawback to osteopathy is the fact that its practitioners, followers, or promoters, have been, and are, far too narrow and exclusive in their pet theories and practice. Drugs, properly used, are unquestionably valuable, as proved by the recorded facts of many decades. Diseases do not originate in the vertebral column, nor can they be cured solely by osteopathic treatment. This is true also when the trouble in the vertebral column is a consequence of some previous disease or toxin. Much besides is required, and other means are often essential to a cure, when used with knowledge and good judgment.

OUR LONDON LETTER.

(From Our Regular Correspondent.)

VARIOUS TYPES OF MENINGOCOCCUS—MEANS OF THEIR DIFFERENTIATION—THE BEST POLYVALENT SERUM—PSEUDOMENINGOCOCCI.

London, September 25, 1917.

It seems now to be generally admitted that the meningococcus discovered in 1897 by Weichselbaum is the infective agent in cerebrospinal fever. Various types of this microbe have been found and described in epidemics of this disease. Different strains of the organism recognized and differentiated by their reactions, some of them so different as to deserve the name of "subspecies." From a clinical point of view the matter is important, as the most promising line of treatment in cerebrospinal fever lies in the administration of the specific antiserum. But to secure that we are using the true specific organism is not always an easy matter—a fact evinced by the too frequent failure of our treatment. The reason of this is doubtless that we have often used samples of serum obtained from different strains of meningococcus—not from the exact type present in the patients under treatment. There have doubtless been many cases in which the serum employed has not been at all specific for the special infection against which it has been employed and consequently it has failed. Practical means for differentiating the types of meningococci have long been sought without success; but Lieutenant-Colonel Gordon has advanced the question, by defining as meningococcus any gram-negative diplococcus that causes primary meningitis, and from that point proceeding to investigate the relations between them by agglutination, using as material organisms isolated from the cerebrospinal fluid of cases of the disease. At first he worked with 3 such organisms and with 14 meningococcus-like organisms isolated from the nasopharynx of contacts, or of cases of suspected cerebrospinal fever. In a second paper (in conjunction with Mr. E. G. Murray) he dealt with 32 more examples of the meningococcus and 9 more Gram-negative cocci indistinguishable from it by cultural and fermentative tests, isolated from the nasopharynx of contacts, or of cases of suspected cerebrospinal fever. A third paper, written by Capt. W. J. Tulloch, summarizes the whole matter and is based on the examination of 107 strains of the meningococcus. By exhaustive tests of their agglutinating powers it has been found possible to refer all, except 6, of these separate strains to 4 main types. The serums he used were obtained by inoculation of rabbits, with the specific strains of meningococci isolated from spinal fluids. A standardized technique was employed and is described in detail.

The bearing of the discrimination is that if we have an epidemic of the disease produced by a group of organisms, each member of the group should have its specific antiserum; alternatively a polyvalent antiserum should be prepared for the broadest treatment of the epidemic.

Captain Tulloch suggests that polyvalent antimeningococcal serums should be richest in the antibodies produced by 2 types of cocci—those occurring most frequently. The ideal method of treating any case would be to give at first the polyvalent serum when lumbar puncture is performed, for diagnosis and as soon as the type of the infecting organism has been settled in the laboratory to continue the treatment by injecting the appropriate specific antiserum. This classification should enable as to draw a clear distinction between true meningococci and some organisms resembling them which are often met with in the nasopharynx, but are not pathogenic. From 6 to 7 per cent of carriers of meningococci were found in a total of over 10,600 contact cases examined in 1915—some observers finding as many as 20 per cent. Captain Tulloch shows as many as 50 per cent. of these carriers may be harboring only the pseudo-meningococcus and

so requiring neither treatment nor isolation. The treatment of cerebrospinal fever may be greatly improved by the discovery of truly specific antiserums and the best treatment now available seems to be the repeated hypodermic or intravenous or intrathecal injection of antimeningococcal serum in considerable doses. Lumbar puncture should be employed at the same time.

LETTER FROM CANADA.

CANADIAN ASSOCIATION FOR THE PREVENTION OF TUBERCULOSIS—CANADIAN PUBLIC HEALTH ASSOCIATION—THE VENEREAL DISEASE PROBLEM—NATIONAL HEALTH INSURANCE—IMMIGRATION PROBLEMS—ANNUAL CONFERENCE OF CHARITIES AND CORRECTION.

TORONTO, Oct. 18, 1917.

THE seventeenth annual convention of the Canadian Association for the Prevention of Tuberculosis took place at Ottawa on Wednesday, Sept. 26, 1917, following a two days' meeting of the Canadian Conference of Charities and Correction. The president, the Hon. J. W. Daniel, M.D., of St. John, New Brunswick, was in the chair.

An interesting report of the year's work was submitted by Dr. George D. Porter, the secretary of the Association, who showed how the war had deepened the general interest in tuberculosis. The situation in France today, where it is estimated that no less than 150,000 soldiers have been invalided by tuberculosis, has demonstrated to the world in general the great importance of preventive measures against this disease. Before the war, with the exception of a few private sanatoria, no steps had been taken in France to prevent the spread of tuberculosis or to make the people realize the danger of infection. In Britain, where preventive measures were already in force, the number of tuberculous soldiers was not so great, although even there by the end of the second year of war 2,770 suffering from this affection had been discharged from the army. In Berlin, it was reported, the death rate from tuberculosis had increased 56 per cent. over that of last year. In Italy preventive measures were being taken by the government, and in Switzerland a sanatorium with accommodation for 2,000 patients was to be established by the International Association. In Canada there were 1,194 tuberculous soldiers under treatment at an average cost of about $1,300 a year for each patient, and of these about 35 per cent. had not been overseas. There were also hundreds of Canadian soldiers who were being treated for the disease in England. The Association had been greatly assisted in its educational campaign by a government allowance which covered the cost of all literature distributed and by franking privileges which had been granted. In addition to pamphlets, reprints of articles on various phases of tuberculosis, copies of the reports of the Association, both in French and English, etc., poster exhibits had been prepared for use in schools, colleges and dispensaries. Since the war began the sanatorium accommodation in Canada, which in 1914 was about 2,000 beds, had been much increased, and the sanatoria already in existence had been enlarged under the direction of the Military Hospitals Commission. Up to the present the anti-tuberculosis movement in Canada had been entirely voluntary, but it was to be hoped that the Government, which had assumed responsibility for the tuberculous soldier, would also recognize its responsibility to the civilian patient and that out of war emergency measures permanent institutions would result. The report concluded with an acknowledgement of the assistance given to the Association by the Imperial Order of Daughters of the Empire and the Victorian Order of Nurses.

The reading of this report was followed by a number of papers on various aspects of the tuberculosis question, among which particular mention might be made of that by Dr. D. A. Stewart of the Ninette Sanatorium at Winnipeg. Under the title "Tuberculosis and Maternity," Dr. Stewart showed how breakdown and loss of resistance prepared a fertile field for disease. In the trenches the men who had become weakened by exposure and privation were the ones to succumb to tuberculosis, just as in civilian life the causes of breakdown were the causes of tuberculosis. Childbirth, when it entailed expenditure beyond the income of the parents, was health bankruptcy. In Canada each year no less than 2,400 tuberculous mothers gave birth to children, and in the province of Ontario 700 of the 63,000 children born in a year were the offspring of mothers suffering from tuberculosis. In the discussion which followed this paper Dr. Adam Wright of Toronto said that no woman suffering from this disease had the right to marry.

The afternoon session was of particular interest in that the papers dealt with the military aspect of tuberculosis. Capt. J. H. Elliott, C.A.M.C., of Toronto, spoke of the prevalence of the disease among members of the Canadian forces (about 3,000 cases have already been reported in England and Canada), and Dr. W. B. Kendall of Gravenhurst, Ontario, reported on the results of treatment. The subject of vocational training was taken up by Capt. R. Roddick Byers, C.A.M.C., of Ste. Agathe, Quebec, and Lieut.-Col. Thompson, M.P., medical superintendent of the Commission, gave an interesting account of what the Military Hospitals Commission is doing for the tuberculous soldier.

The presidential address was delivered at the evening session by the Hon. J. W. Daniel, M.D., of St. John, New Brunswick, who in speaking of the work accomplished by the association, reminded his hearers that in the province of Ontario the death rate from tuberculosis had been reduced from 149 to 91 per 100,000. The public address was given by Dr. W. A. Evans of Chicago, the president of the American Public Health Association, who, in simple and direct language, suggested ways and means of preventing the onset and spread of the disease.

Resolutions were passed in favor of the establishment of tuberculosis clinics, the extension of the antituberculosis movement toward the training and for the protection of the youth of the country, the examination of recruits by chest specialists, and the pasteurization of all milk and cream used in the manufacture of butter and cheese. The establishment of a Federal Bureau of Public Health was urged upon the Government.

Dr. J. A. Machado, of Ottawa, was elected to the presidential chair for the year 1917-18.

The sixth annual congress of the Canadian Public Health Association was held at Ottawa on September 27 and 28, under the presidency of Dr. J. D. Pagé, Chief Immigation Officer, Quebec. Among the subjects that came up for discussion in the course of an excellent program were two that are of particular importance at this time—the problem of venereal disease and National Health Insurance. Referring to the alarming prevalence of venereal disease throughout the country, Captain Gordon Bates, C.A.M.C., of Toronto, said that the true facts should be laid frankly before the public and a law passed similar to the Western Australian Act. Periodical inspection and quarantine had been adopted in the army and it was time that more efficient measures were enforced among the civilian population. Major Lauterman, C.A.M.C., of Montreal, emphasized the importance of educating the public to a realization of such disease as "the greatest menace of the civilized world." (A campaign against venereal disease has been inaugurated in Toronto and a few days ago two deputations waited upon the government with the request that such disease be classed as contagious and be made subject to the regulations governing diseases of that nature.)

The symposium on health insurance was of unusual interest, since it really constituted the beginning of an educational campaign in Canada, and moreover was the first lengthy discussion of the subject at a medical meeting in that country. Dr. Hastings, of Toronto, expressed himself in favor of an Insurance Act on the lines of the one introduced in England by the present premier and now working so successfully. It had been estimated, he said, that the average loss of time to the working man through sickness was nine days a year, which meant in Canada an annual economic loss of over $64,800,000. It was impossible for the large proportion of unskilled workers to obtain proper medical attention under existing conditions. Under an efficient health insurance system an employee disabled by accident or sickness would receive $7 a week for a period not exceeding twenty-six weeks in one year, adequate medical and surgical attention, proper medical attention of wife during confinement, and a death benefit of $100. Such a system pointed the way to a new democracy ensuring freedom and justice to all classes. It should be noted here that the attention of the profession was directed toward this question by the president of the Canadian Medical Association on the occasion of the annual meeting of that Association in Montreal in June.

In the presidential address Dr. Pagé dwelt at some length upon immigration problems as they concern the Canadian people. He laid emphasis on the fact that methods of inspection of immigrants to Canada were not nearly so effective as those employed in the United States, where responsibility for the class of immigrants is placed with the steamship companies. Dr. Pagé deplored the indifference of the people in respect to public health problems. He thought that, much as it was needed, a department of public health could be established only when public opinion awoke to the true facts of the situation and demanded such a department.

A number of other subjects bearing on different phases of public health work were discussed and, in the laboratory section, a provisional draft of the report of the Committee on Standard Methods of Water Analysis was presented by Mr. Joseph Race of Ottawa. Dr. W. H. Hattie, of Halifax, Nova Scotia, was elected president of the Association for the year 1917-18.

At the Annual Conference of Charities and Correction which took place at Ottawa on September 24 and 25, Dr. Clarence M. Hincks, secretary of the Ontario Association for the Care of the Feebleminded, made a strong plea for the segregation of the mentally deficient. Protest was made by the Mayor of Ottawa against the continuation of the sale of intoxicants at Hull, which, though in the province of Quebec, lies just across the river from Ottawa. It was moved by the Committee on Resolutions that all children born out of wedlock should be given the father's name and should be entitled to inheritances from the parents.

2. Indications for Operations on Traumatic Head Cases.—Edward H. Nichols states that the lesions produced by trauma of the head are numerous and include: (1 Edema of the brain due to vasomotor disturbances. (2) Slight laceration of the brain, practically always accompanied by edema. (3) Local extracerebral hemorrhage, either subdural or extradural, generally frontal or temporal, and often slight in amount, also accompanied by edema. (4) Local extracerebral hemorrhage of great amount, subdural or extradural, generally due to rupture of the middle meningeal artery, also most often temporal or parietal, again accompanied by edema, sometimes with, sometimes without fracture of the skull. (5) Diffuse extracerebral hemorrhage, usually at the base of the brain, generally due to rupture of one of the cerebral sinuses, usually associated with fracture of the base of the skull, and frequently accompanied by a resulting pressure upon or division of one or more of the cerebral nerves. (6) Severe intracerebral hemorrhage, due to rupture of cerebral vessels, practically always associated with extensive fracture of the skull. (7) Fractures of the skull which vary from a mere fissure, often detected only by *x*-ray, or by local swelling, or tenderness, to depressed fracture, sometimes only of the outer table, often involving the entire thickness of the skull, not infrequently compounded; and, finally, fractures of the base of the skull. These latter fractures are usually associated with rupture of one of the cerebral sinuses. These latter fractures are usually produced by compression. In these cases various injuries of the cerebral nerves may occur, most often the 6th (abducens) and 7th (facial). A fact to be emphasized is that the fracture usually is of secondary importance; the brain injury is the serious factor. The symptoms are as follows: (1) Edema of the brain, if uncomplicated, produces symptoms best described under the clinical term *concussion*. These symptoms vary from slight mental confusion to temporary, sometimes prolonged, unconsciousness, or symptoms of

cerebral irritation, delirium, and excitability. Such symptoms generally are produced by a blow on the head of moderate severity, a blow, a fall, football collisions, etc. As a result, it is claimed that vasomotor disturbance of the brain vessels is produced, serum escapes from unruptured vessels, and as the result there is an extra amount of fluid in the brain, and since the skull is unyielding, pressure on the brain occurs. The mental symptoms are variable, depending upon the degree of edema. There may be a very temporary mental confusion, the patient may talk rationally on simple subjects, but there nearly always is some difficulty in orienting himself,—he cannot tell where he is, the day of the week or month, etc. There practically always is some loss of memory of preceding events, *e. g.* the patient cannot remember what he had to eat at the preceding meal, or, in severe cases, cannot recall ordinary events that occurred during the twenty-four hours preceding the injury, and often cannot remember events for a shorter time succeeding the injury. A notable fact regarding the loss of memory is that the so-to-speak "lost time" gradually becomes less as the patient recovers, but a *complete* restoration of memory seldom occurs, even in mild cases. The "automatic" memory often is fairly good, even though actual memory is quite gone. Or the edema may produce cerebral irritation, manifested by excitability, or delirium, and the patient in this condition may become violent and assault bystanders, and occasionally such cases are dangerous. If the edema is severe, unconsciousness may result, partial or complete, but these cases always can be roused, at least partially, by supra-orbital pressure. Vomiting is frequent. The pupils are equal and react, often violently, and usually are dilated; the face is pale, the patient restless and irritable. The *temperature is low*, normal or subnormal, and the pulse rapid. The blood pressure is nearly always low. The spinal fluid is clear and contains no blood. The unconsciousness seldom lasts over twenty-four hours, although some confusion may last longer, and in many of these cases neurasthenic symptoms may last for a considerable time and many of these patients cannot study or do work requiring close mental application for many months. Nichols summarizes his treatments as follows: (1) Uncomplicated edema of the brain almost never requires operation. (2) Slight laceration of the brain with persisting edema sometimes requires operation to prevent cerebral degeneration. Subtemporal method is the best operation. (3) Slight extracerebral hemorrhage seldom requires operation; occasionally demands operation to avoid cyst formation; the operation of choice is always skin-bone-flap. (4) Extensive extracerebral hemorrhage, from rupture of the middle meningeal artery, with or without focal symptoms, *always* should be operated on, and always by skin-bone-flap method. (5) Basilar hemorrhage seldom can be cured by operation. When operation is done it should be done on selected cases, for relief of pressure, and usually by skin-bone-flap method. (6) Intracerebral hemorrhage cannot be cured by operation, although pressure may be relieved. (7) Fracture of the skull, by itself, is of little importance except when compounded, in which case it may be followed by meningitis unless it is promptly made aseptic. All depressed fractures involving the entire thickness of the skull should be elevated.

3. **The Temperature As a Valuable Guide to Diagnosis, Prognosis and Surgical Treatment in Craniocerebral Traumatisms.**—J. W. Courtney gives the menace of a skull fracture as twofold: By its site it may invite infection, and by its character it may create serious brain irritation or compression. The error most commonly committed by neurologist and surgeon alike is to allow their attention to become engrossed with phenomena which spring from disturbance in or destruction of functionally well-known areas in cortex or elsewhere, while they overlook the supremely important fact that lesions identical in kind with those responsible for these phenomena may be wrought at the same time by the same force in widely scattered *silent* regions of the encephalon. This is a point upon which neither too great nor too frequent emphasis can be laid. Personal experience leads him to declare dogmatically that, of all the diagnostic and prognostic manifestations of intracranial traumatisms, the temperature throughout stands supreme in the scale of importance. Pulse and respiration are not negligible quantities, but a depression of cardiac force is no more significant here than in other forms of injury or disease. Speaking generally, with regard to the pulse in the injuries in question, it is entirely justifiable to say that a practically normal or a full and relatively slow pulse is encountered as often in recovering cases as in those which turn out badly. As to respiration, it is usually a most unreliable measure of the degree of danger that menaces, except in initial shock or in the closing phase of a fatal case. On the other hand, for precious indications, both of a diagnostic and prognostic order, one may confidently look to the temperature. Let us study first its behavior in intracranial hemorrhage. The immediate effect of this, as of other forms of traumatic intracranial lesions, is to produce shock, with its concomitant subnormal temperature. Unless, however, the bleeding is very extensive and complicated by coexisting alcoholic intoxication, the temperature soon regains the normal and is seldom elevated more than a single degree throughout the entire course of the case, provided no extensive degree of contusion and no degree whatsoever of laceration be present. In uncomplicated contusion the range of the temperature is equally distinctive. In the generality of cases it rises quickly from the subnormal point caused by shock and may go as high as 102. Almost from the beginning its recessions are striking. On the morning of the day following the receipt of the trauma it may drop to 99, or even to normal, only to rise again in the evening to 101 or 101.5. The next morning may find it at 97.5; the evening at 99, or even 100. Throughout the whole duration of the case its behavior is consistent. In favorable cases the evening range gradually narrows to the normal point, the morning recession to a point but slightly subnormal. Toward the end, in unfavorable cases, temperature and pulse rise together and may reach a very high point. In brain laceration the initial fall of temperature from shock is of extremely brief duration. It makes little practical difference whether the tearing of brain tissue occurs in alleged heat-producing centers or elsewhere, or whether this tearing is associated with a considerable hemorrhage. In every case of laceration, regardless of surrounding conditions, the almost immediate trend of the temperature is steadily upward. And in severe cases it may rise to 104 or 105 in a few hours. In general it does not rise so quickly to this height. There may even be, in the course of a few days, recessions, but these are infrequent and insignificant. The fact remains that an early and persistently high temperature after craniocerebral traumatism invariably denotes brain laceration. He states categorically that the occurrence of chills during the course of a case of head injury is decidedly not an indication of pus formation. In arachnitis they are mainly conspicuous by their absence, but in uncomplicated contusions are often present. The development of an arachnitic process is, in general, seldom discernible for several days after the receipt of the trauma. Its onset is marked by a sudden jump in the temperature accompanied by such signs of cortical irritation as delirium, somnolence or great motor restlessness. The initial rise may be as much as 6° in a few hours. This more or less sudden and sharp elevation occurring at the epoch above indicated is, in and of itself, distinctive. Even more so, however, are the curious fluctuations in temperature which succeed it. Not only from day to day, but from hour to hour are these observable; and there may be a difference of 4° in the highest and lowest points noted in the space of twenty-four hours. The average temperature may be as high as 103° plus. In cerebral abscess the behavior of the temperature may be broadly outlined as follows: It is normal during a sinister period of quiescence which follows the antecedent activity of the process, whatever it may be, that prepares the soil for the growth of pyogenic organisms, and *subnormal* after an abscess has attained sufficient proportions to cause local manifestations of its presence. One must not, however, adhere rigidly to this formula in all cases. In certain cases development of an abscess may take place before the signs of an antecedent process have disappeared. In this event the temperature may continue high to the end.

1. The Psychological and Therapeutic Value of Studying Mental Content During and Following Epileptic Attacks.—L. Pierce Clark states that from past studies we have learned that a large number of individuals who suffer from essential epilepsy have epileptic reactions which range in severity from passionate episodes to the severest grand mal seizures. These are a result of a certain type of egoistic, sensitive, and poorly adaptive makeup, plus some irritative stress or demand that seems to act as a precipitating cause for the epileptic seizure. While there are many important phases of the physical and mental makeup of the epileptic constitution to be made clear, we should continue to study all the mental factors, both immediate and remote, which appear to initiate attacks in epilepsy. He summarizes the results of his study as follows: It would seem as though in many individuals suffering from essential or idiopathic epilepsy there is a peculiar type of makeup antedating the disorder, and that the frank epileptic attacks are but a more pronounced manifestation of this character makeup. The attacks are often induced by certain and varied types of stress, exogenous as well as endogenous, but the former have not been given the attention their importance demands. The mental content immediately after the convulsive part of the fit, either spontaneous or brought out by questioning, gives data highly important for studying the unconscious strivings as well as the patient's construction of the way by which he thinks he may overcome his malady. It also gives points upon which we may base psychopatherapeutic talks of signal aid in enabling the patient to better cope with his gigantic handicap of maladaptation to the stresses of life. This brief and fragmentary study of the mental content of definite though mild reaction episodes in a few epileptic cases show that the work is enormously complicated, as varying depths of consciousness may be tapped, as it were, even in the one patient and in the one attack. As our psychanalytic knowledge of the dream problem as well as of the mental content of many of the psychoses grows, the field sketched here will be found more necessary for scientific and therapeutic study.

9. The Use of Bakers' Yeast in Diseases of the Skin and of the Gastrointestinal Tract.—Philip B. Hawk, Frank Crozier Knowles, Martin E. Rehfuss, and James A. Clarke in collaboration with four other scientists have worked out the effect of this form of treatment in skin diseases and gastrointestinal conditions and further state that yeast possesses properties of curative types that were appreciated in the olden times. Hippocrates recommended its use in leucorrhea, and the monks used it for the treatment of plague. Not, however, until the middle of the nineteenth century did the medical profession look favorably on its use. About that time it was used successfully in furunculosis, anthrax, and diabetes. Later it was used in diseases of the skin, suppurative processes, respiratory conditions, gastrointestinal troubles, vaginitis, and general infectious diseases. In all of their tests Fleischmann's compressed yeast was used, the fresh yeast being secured from two to three times a week and kept in the refrigerator until used. A study of ninety-one cases was made. Tests were also made on normal persons to learn the action of yeast in the stomach when suspended in water, beef tea or orange juice, with meals or between meals. The comparative effect of living and dead yeast was studied. The yeast was killed by treating it with boiling water for a few minutes. All stomach examinations were made by means of the fractional method. From the tests it was found that yeast may be administered satisfactorily either with meals or on the empty stomach; that killed yeast acts much the same in the stomach as living yeast. If the patient is troubled with gas formation it is preferable to use killed yeast, or to administer living yeast between meals. These tests also demonstrated conclusively that yeast is not readily destroyed in the human stomach, but that on the contrary, especially when taken between meals, a large part of the yeast passes into the intestine in the living condition. Hence, it is possible that in certain disorders, especially those involving constipation, the living yeast has a more pronounced action than dead yeast. The average dosage was one-half to one cake three times a day after meals, or before meals if the condition so indicated. The length of treatment ran from one to three weeks. These investigators draw the following conclusions as the result of their experimental data: (1) Bakers' yeast was found to be a useful remedy in the treatment of furunculosis, acne vulgaris, acne rosacea, constipation and in certain other cutaneous and gastrointestinal conditions. (2) The conditions which respond most favorably to the yeast treatment were (*a*) furunculosis, (*b*) the acnes (vulgaris and rosacea), and (*c*) constipation. Of seventeen cases of furunculosis, all but one of the patients were improved or cured. Of seventeen cases of acne vulgaris all patients were improved or cured. Of eight cases of acne rosacea, all patients were improved or cured. Of ten cases of constipation, nine were improved or cured. In other words, fifty out of fifty-two cases of furunculosis, the acnes, and constipation were improved or cured by yeast treatment. (3) We consider that yeast is fully as successful as any other remedy in furunculosis, acne vulgaris and acne rosacea. (4) In many of the cases which came under observation, the yeast treatment caused an improvement in the general physical condition of the patient quite unassociated with the improvement of the symptoms associated, with the particular disease in question.

2. A Clinical Lecture on Some Nose and Throat Diseases of Childhood.—Douglas Guthrie first discusses adenoids and tonsils and states that a lightning diagnosis is seldom a satisfactory proceeding. While the facial expressions, especially in children, are well worth studying, he warns that the adenoid facies is not invariably diagnostic of adenoids. A certain amount of adenoid tissue is present in the nasopharynx of every child, and

between the ages of two and ten it is very liable to hypertrophy. Over 90 per cent. of the children brought to the ear and throat clinic and his hospital suffer from adenoids, and the frequency of adenoids among children of school age has been estimated at 30 to 40 per cent. The symptoms are varied. Among all the well-known symptoms a flow of white gummy mucus from behind the soft palate is often a sign of adenoids, and sometimes a glimpse of the growths may be obtained in a post-nasal mirror. By attention to these points the disagreeable procedure of palpating the nasopharynx may be avoided, a procedure for which no child will ever forgive its doctor. In every child suffering from enlarged tonsils the tonsillar gland is palpable behind the angle of the jaw. This is a significant fact, and the important point to remember is that the tonsils and associated adenoids should be removed before the tubercle bacillus gains admission to the gland through the diseased tonsil. The tonsils should be attended to in all cases of enlarged cervical glands. Another childhood disease which should always lead to examination of the tonsils is that of rheumatism. "Growing pains" in a child should mean in the majority of instances the removal of the tonsils. The tonsil operation is outlined as follows: Having administered ethyl chloride, introduce the guillotine with its upper surface toward the tonsil, thread it over the tonsil, and dig the point of the instrument well in behind the tonsil, then lever the tonsil forward so as to produce a swelling on the palate; press upon this swelling with the left thumb, thus forcing the tonsil through the ring of the guillotine. Lastly, drive home the blade and withdraw the guillotine with its lower surface, carrying the tonsil, uppermost. After removing the tonsils, hook the curette well up behind the palate and shave off the adenoids with a downward sweep. Foreign bodies in the nose often produce symptoms resembling adenoids. The presence of a foreign body in this locality produces a unilateral discharge. Foreign bodies in the lower respiratory tract produce symptoms of a more serious nature. They usually lodge in the larynx and the right bronchus. As regards the larynx there may be no history of foreign body, but the child may be thought to be suffering from diphtheria or simple laryngitis. When a foreign body passes the larynx it usually lodges in the right bronchus, which is not only wider than the left bronchus, but lies in a more direct line with the trachea. Bronchoscopy is by no means an easy operation, but should be immediately performed in order to prevent complications in the lung. Should the direct method be unavailable tracheotomy had better be performed, as this operation has been proved to have a favorable influence on the mortality rate. Not infrequently the foreign body is coughed out through the tracheotomy wound. Coins are often impacted at the entrance to the esophagus in the postcricoid region. For relief a coin-catcher, or better, the more modern and scientific method of esophagoscopy may be employed. Guthrie directs attention to diseases of the larynx in small children, because of their difficulty of diagnosis. The child's larynx is a smaller structure than might be supposed, and its cartilages are very soft, hence stenosis and suffocation are more liable to occur than in adults. Laryngoscopy is more difficult. The inferior turbinal bone in the nose is a similar offender, and is sometimes mistaken for a polypus. Nasal polypus is very rare in childhood. Laryngeal stridor is another affection of infancy. It commences at birth or shortly after and is due to a backward development of the larynx. The epiglottis is sharply folded upon itself and the arytenoids are closely approximated so that the upper aperture of the larynx is narrowed. No treatment is required as the condition tends to disappear during the second year of childhood. Papilloma of the larynx is a possible cause of obstruction in children. Its diagnosis is difficult, tracheotomy is often necessary, and the growths are very liable to recur after removal.

1. The Meningococcus of Weichselbaum.—Edward C. Hort states that notwithstanding the results of recent experimental research, it is still taught, and it is in consequence widely believed, that the meningococcus of Weichselbaum is itself the direct causal agent of that form of epidemic cerebrospinal fever which is sometimes spoken of as meningococcal meningitis. It is also still taught, and the teaching is accepted without question, that the meningococcus, as one of the "lower" bacteria, is an organism with an extremely simple life-cycle, which begins and ends with binary fission into two equal parts. A meningococcus—so runs the legend—always arises directly from a meningococcus, and in no other way. As regards the first of these propositions—that the meningococcus is itself the direct cause of the disease which bears its name—he showed by experiment in 1915, and this, in conjunction with Captain A. H. Caulfeild, he amply confirmed in the following year: (1) That cultures of the meningococcus in cerebrospinal fluid or in suitable laboratory media frequently contain a minute filterable virus, which is just as pathogenic to monkeys (though not necessarily productive of meningitis) as are unfiltered cultures. (2) That the meningococcus itself appears to be inert, in so far as the production of systemic infection is concerned, whether the cultures be of the so-called epidemic strains, or of admittedly harmless types of carrier strains. As a result of these experiments, it became clear that the pathogenic results obtained in the past by injection into animals of living cultures of the meningococcus, believed at the time of injection to be pure cultures, are in reality to be ascribed to the injection of impure cultures, the "impurity" consisting in the minute filterable virus described. It became manifest, in short, as a result of these experiments, that there is no reliable evidence that the meningococcus as such is itself responsible for the disease, mere constancy of presence of the organism, even when combined with agglutinability, being of little value as proof of direct etiological relationship. Demonstration of the presence of this filterable virus in meningococcal cultures had, moreover, this important result, that it threw grave doubt on the validity of the second proposition, namely, that the reputed causal organism of the disease is a bacterium with a simple life-cycle, which begins and ends with equal binary fission. It unmistakably suggested, in fact, that the meningococcus represents one phase only—the filterable virus representing a second phase—in the life-cycle of an organism which has not yet been described, though, owing to the fact that the experimental method of investigation was mainly employed, it was not then possible to prove by ocular demonstration that this is indeed the case. To-day, as a result of direct morphological studies of cultures of the meningococcus—studies which are capable of ready verification by the adoption of an extremely simple technique—Hort has been able to confirm and amplify the results obtained already by the experimental method. He can now produce direct morphological evidence that the meningococcus is not a bacterium at all, and that both it and the filterable virus referred to do actually represent different phases in the life-cycle of an ascomycetic organism, which has hitherto been believed to be an involution form of the meningococcus. Even now the complete life-cycle in the human host of the causal organism (of which the meningococcus only represents a saprophytic phase) of cerebrospinal fever has not been worked out, and much yet remains to be done. Hort in this communication deals chiefly with the morphological characters of the meningococcus and its so-called giant forms. The morphological characteristics of the meningococcus were studied as developed in liquid cultures; examination of the unstained living organisms at room temperature; examination of stained fixed films; examination of unstained fixed films by the Congo Red method, and examination of the living organisms at room temperature and on the warm stage. Details of the technique employed are given, together with illustrative fermenta-

tion and serological tests of the serum-broth cultures employed in the above observations. As the result of such comprehensive work Hort draws the following conclusions: (1) The so-called giant meningococcus is not a bacterium. It represents an ascal stage in the life-cycle of an organism allied to the ascomycetes. The ascus may be either large or small, or of any intermediate size (0.2μ to 5μ). (2) The meningococcus of Weichselbaum is not a bacterium. It is an ascospore, derived from the "giant meningococcus" by a process of endosporulation. (3) The filterable meningococcal virus of my earlier papers probably represents a stage in the life-cycle of the ascomycetic organism described. (4) The true nature of the meningococcus and its alleged giant forms has hitherto been missed because of the practically exclusive use of solid media for purposes of identification, and because direct examination of unstained living organisms, including warm-stage development in liquid cultures, has not been carried out.

La Presse Médicale.

August 30, 1917.

The Warfare Against Tuberculosis.—Danysz states that we are not availing ourselves of the latest developments in our knowledge of pathology. Four substances present themselves for consideration: I. Tuberculine prepared *in vitro* from bacilli. II. The natural tuberculine in the blood of patients. III. Normal antigen which combines within the cells with tuberculine. IV. Antituberculine or excess of the preceding. Concerning these we know that artificial tuberculine does not act upon healthy tissues and repeated injections of it never produce antituberculine. We also know that natural tuberculine is pathogenic to the tissues after an interval of lateney and that it provokes the formation of antituberculine (specific antibody in excess) as shown by the reaction of fixation in the blood and the cutireaction in the skin. The microorganisms of the disease in a focus of disease secrete natural tuberculine which in part is fixed by the cells of the surrounding tissues. The unused excess enters the blood as antituberculin. The resulting immunity, however, is associated with a sensitizing of the body cells toward numerous substances and forces, comprising temperature changes, fatigue, various bacteria, toxins and even drugs (creosote). If after the development of specific immunity the subject shows active manifestations of the disease it amounts to a reinfection and connotes that the subject has actually been cured; also that immunity was of short duration. Animal experiment shows that a certain amount of protection can be obtained by the injection of dead cultures or of living, avirulent cultures, but the mechanism differs widely from that employed by Nature. Thus special antibodies are formed which agglutinate and precipitate the bacilli. But this method cannot rationally be used to immunize healthy subjects, and the author looks forward to the possibility that the latter aim will be secured by the exhibition of vaccine *per os*. In regard to future therapy he at present looks hopefully toward the use of such old remedies as creosote and its derivatives, and of new substances such as the double cyanide of copper and potassium.

Il Policlinico.

August 15, 1917.

Woody Phlegmon.—Filardi outlines the literature of this subject from the time (1891) when Reclus reported the earliest cases. The condition, while due to pyogenic cocci of low virulence, bears considerable resemblance to the lesions of actinomycosis. Another affection which stands in some relationship to the woody phlegmon is the so-called inflammatory pseudoneoplasm, which at times is seen to follow abdominal section and from its rapid growth may simulate malignancy. Despite the difference in the course, etc., of these affections there are present a number of points in common. The pseudoneoplasm has been known to form about a foreign body—in fact, there is on record an entire series of such cases. The woody phlegmon may appear in any locality, and hence is sometimes seen in the abdominal wall, while the pseudo-neoplasm seems to occur nearly always in the latter and when it projects inwardly may give rise to pressure symptoms or ileus. Recently cases of woody phlegmon have also been found to be due to the presence of foreign bodies and pseudo-neoplasms have been found to originate within the abdomen. It is becoming increasingly evident that the two types of lesion, while in some ways independent, shade very closely into each other. The author reports two cases as examples of woody phlegmon. The first occurred in the right lower abdominal quadrant and was very large and extremely hard. The young man had suffered from pain in the ileocecal region for four years. One year ago he first remarked the presence of a tumor. The diagnosis was made of tuberculous psoas abscess. Operation confirmed it, but there was no vertebral caries. Several months later symptoms appeared which led eventually to the diagnosis of cancer of the ascending colon. This was not concurred in by the author when the case was referred to him. He merely postulated the existence of a second cold abscess. Laparotomy showed the presence of a tumor-like mass, which upon puncture gave exit to a little pus from a small central cavity. A bacteriological examination showed the presence of the staphylococcus, while a histological study showed the absence of granulomatous, tuberculous or tumor tissue. The growth was of purely inflammatory origin with no evidence of foreign body. There was absolutely no apparent cause. The second case in an old man followed an operation for inguinal hernia, and the diagnosis had been malignancy. The lesion was a duplicate of that of the first case and also due to the staphylococcus.

Rhinogenic Affections of the Optic Nerve.—Galtung recalls that a century ago Beer called attention to this association, but many years elapsed before it received serious consideration. Eventually separate literatures sprang up, ophthalmological and rhinological. Onodi studied extensively the anatomical relationship between the optic canal and the accessory nasal sinusis and showed that one optic canal could at times stand in definite relationship with the sinuses of both sides. *Vice versa* affections of the sinuses of one side can be associated with bilateral involvement of the opticus. Both blood vessels and lymphatics can play important rôles in the extension of disease processes. If the posterior sinuses of both sides stand in communication with the chiasm hemianopsia may result—bitemporal, binasal, unilateral and homonymous. Ordinary scotomata, central and paracentral, may appear in the visual field. Similarly various scotomata for white and colors may be produced, and the percentage of this incidence in rhinogenic affections may be very high. In sinus empyema it has reached nearly 50. Cases are reported which bring out many of the points involved. A patient was admitted with left retrobulbar neuritis. The nose was carefully examined with negative results. The condition in the nerve progressed and the opposite side had become involved before the author was consulted. A test for scotoma of the type found in these cases had been impracticable. The author, who is a rhinologist, found the nasal chambers normal, but there was a right ethmoiditis in both anterior and posterior cells in which pus was present. This condition did not prove that the patient's threatened blindness was of nasal origin. A neurologist could have with much probability diagnosticated multiple sclerosis (lues could be excluded). Intranasal treatment was vigorously carried out and from analogy the patient should improve; *i.e.*, treatment instituted in season has given very good results considering the seriousness of the outlook. In a second case the patient was suddenly stricken blind after an attack of nephritis. Examination revealed the presence of a bilateral peripapillary scotoma, and in addition a paracentral temporal scotoma. Neurological examination negative. The nasal chambers, maxillary and frontal sinuses were normal. In the anterior ethmoidal cells a mucocele was present. Patient received vigorous intranasal treatment and eventually the scotomata disappeared and the visual field became normal to the ophthalmoscope. The color vision, originally normal, had now become affected and patient had become blind to red and green.

Book Reviews.

Linfadenias en la Infancia. Por el Dr. Juan Carlos Navarro. Buenos Aires: Libraria "Las Ciencias," 1916.

The author of this monograph is a pediatrist who has published numerous articles on subjects pertaining to his specialty. In addition to the several well-known clinical types of lymphadenia the author includes chloroma, myeloma, the lymphosarcomatosis of Kundrat, granulomatosis, tuberculous and syphilitic granuloma of the lymph nodes, generalized endothelioma of the same, and finally a systematized gangliomic affection first described by Dr. Elizalde of Argentina. The book is well planned and executed and is doubtless unique in presenting all the forms of neoplasia not only of the ganglions proper but other lymphoid tissues, as limited to childhood. The research into literature is extensive. Two personal cases are described—one of the localized form of lymphogranulomatosis and the other of Kundrat's lymphosarcomatosis.

The Tree of Life. An Exposé of Physical Regenesis on the Threefold Plane of Bodily, Chemical, and Spiritual Operation. By George W. Carey, author of Text-Books on the Chemistry of Life. Price, $1. Los Angeles: Dr. George W. Carey, 1917.

It is enough to say of this book that it seeks to give a mystical interpretation to recent scientific discoveries. The author finds it advisable to rewrite etymologies. He derives the "mass" and "mason" from a root meaning dough; but the letter N in Hebrew means fish, and putting the N in mason is responsible for the friction between Catholics and Masons. Fish is symbolic of Christ, hence immaterial, while dough is material. Much of this symbolism is very old.

Food Preparedness for the United States. By Charles O'Brien. Boston: Little, Brown, & Co., 1917.

This little book, dedicated to Horace Fletcher, is a first rate summary of the problem of food preparedness for those who are not well informed on the subject. The medical reading man will probably not find much in the book which is actually new. The author, while a layman, steers clear of all medical solecisms, and the only point to criticise is a passage in which loss of weight seems to be regarded as equivalent to loss of adipose. Loss of water must be carefully distinguished from loss of fat.

Operative Surgery of the Nose, Throat, and Ear for Laryngologists, Rhinologists, Otologists, and Surgeons. By Hanau W. Loeb, A.M., M.D., Professor of Ear, Nose, and Throat Diseases in St. Louis University, in collaboration with Joseph C. Beck, George W. Crile, and Others. In two volumes. Vol. II. 476 illustrations. Price, $7.00. St. Louis: C. V. Mosby Company, 1917.

The second volume of this well-known work deals with the operative surgery of the nasal chambers and sinuses, pharynx, larynx, ear and mastoid process. It will be recalled that the earlier volume dealt chiefly with pathology and exploration, and that operative procedures were limited to plastic work on the nose, ear, etc. Volume II. therefore constitutes a separate work on operative surgery. The collaborators of the author in the second volume are Beck of Chicago, Haskin of New York, Levy of Denver and Richards of Fall River. Surgery of the nose naturally includes surgery of the hypophysis by the nasal route and all the other major operations involving the bones which enter into the formation of the nasal fossæ. Operations for cleft palate are properly omitted as belonging to oral surgery.

Operative surgery of the pharynx deals with adenoidectomy, tonsillectomy, and operations for growths in the nasopharynx. The older haphazard methods of excision of a portion of the tonsil have largely given way to dissecting and suture procedures which combine both the radical and conservative viewpoints.

Intralaryngeal intervention is limited to surgery of the larynx proper. Bronchoscopy is considered in Volume I, including extraction of foreign bodies in the bronchi.

Operative surgery of the ear is made up chiefly of interventions in the mastoid process and comprises a full account of intracranial surgery for otogenic conditions, including spinal puncture and surgery of the cranial vault.

It will always be a matter of opinion whether a single class of men should by implication cover the surgery of so many different localities at the same time; but in the smaller cities such a custom is universal and a work of this sort is extremely convenient for this already large and rapidly increasing class of specialists, for which, no doubt, the book was chiefly published.

University of Iowa Monographs. Studies in Medicine. First Series, Volume I, No. 10. Professor Henry Albert, M.D., Editor. Price, 40 cents. Published by the University, September, 1917.

This number of the Monographs contains thirteen original articles, all of which have already been published in well known medical periodicals during 1916-1917. Perhaps the most significant deals with the recent appearance of exanthematic typhus in Iowa, apparently for the first time. No problem is present, however, for the disease was simply an extension of Mexican typhus through intermediate states to Iowa by Mexican railway laborers.

The Small Community Hospital. A Series of Eight Papers by John Allan Hornsby, M.D., Editor of *The Modern Hospital*. St. Louis: The Modern Hospital Company, 1917.

The eight papers referred to comprise from first to last the creation or backing of the hospital as based on a community survey; the financing; the planning; the construction; the interior; the equipment; the organization and the resident personnel. Hospitals of this scope would probably come in a short time to have an average daily number of ten to twenty patients. In the plans given there are accommodations for twelve ward patients and three private room patients. The size and elaboration of the plant required to take care of this small number of patients would seem to a novice to be all out of proportion to the latter's requirements, but a small hospital must have everything which is really essential to proper operation and differs from the large institution chiefly in the number of guests.

The Practical Medicine Series. Volume III. The Eye, Ear, Nose, and Throat. Edited by Casey A. Wood, C.M., M.D., D.C.L., Albert H. Andrews, M.D., George E. Shambaugh, M.D. Series, 1917. Price, $1.50. Chicago: The Year Book Publishers, 1917.

Dr. Wood's section on the eye occupies one half of the book and is the only one to receive a preface, which calls attention to the importance of military ophthalmology at the present time. This section comprises over 100 abstracts from current literature, very many of which are suitably illustrated. The section on the ear could have been expanded considerably by reproducing more abstracts on the innumerable tests for simulation and military otology in general is not given much space (for example, we see no reference to the ear troubles of aviators). The nose and throat each receive separate consideration and the same sort of criticism applies equally to them.

Examination of Water, Chemical and Bacteriological. By William P. Mason, Professor of Chemistry, Rensselaer Polytechnic Institute; Member of the American Philosophical Society, the American Chemical Society, the American Public Health Association, the Royal Sanitary Institute, Great Britain; Honorary Member Association Générale des Hygiènistes et Techniciens Municipaux, the American Society of Civil Engineers, the American Water Works Association, the New England Water Works Association, the American Institute Chemical Engineers, the Franklin Institute, etc., etc. Fifth Edition, thoroughly revised. Price, $1.25. New York: John Wiley and Sons, 1917.

This work dealing with the examination of water by Professor Mason is practical and clearly expressed. All matter which does not directly deal with sanitary examination of water is left out. This, the fifth edition, has been brought into conformity with modern practice and may be recommended as a handy reference book concerning the subject with which it deals.

Society Reports.

NEW YORK ACADEMY OF MEDICINE.

SECTION ON SURGERY.

Stated Meeting, Held October 5, 1917.

DR. EDWARD W. PETERSON IN THE CHAIR.

Intussusception of the Appendix. — Dr. CHARLES E. FARR presented this case. He stated that the patient, a little girl 5 years of age, was admitted to the hospital with the history that four days previously she had had a sudden attack of pain in the abdomen, with repeated vomiting. Her bowels moved with difficulty, but there was no blood or mucus present at any time. There was considerable leucocytosis. The *x*-ray picture gave no definite information. Palpation of the abdomen showed a movable lump in the right iliac fossa. The case was diagnosed as one of appendicitis with mild obstruction. At operation it was found that the appendix had gone into the cecum and would neither go further in nor come out. Hence a resection of that portion of the cecum around the appendix was made, after which the patient made a good recovery. The cecum was edematous over an area from one and one-half to two inches in diameter. The case was reported because it was rather unusual to find an intussusception of the appendix into the cecum. Intussusception at the ileocecal valve or in the region of the sigmoid was quite common. In this case the ileum was not involved. Dr. Farr stated that there were 26 cases of intussusception of the appendix on record which Dr. Moschcowitz had collected and included in a paper in which he reported a case coming under his observation. He had heard of one or two other cases, so that while this form of intussusception was not extremely rare it occurred far less frequently than other forms of intussusception.

Hemiplegia and Aphasia Caused by Subdural Hemorrhage; Osteoplastic Flap; Recovery.—Dr. ANTHONY H. HARRIGAN presented this patient, a woman 40 years of age, who was admitted to the Fordham Hospital on August 2, 1913. He said that the injury was the result of an automobile accident, and that when brought to the hospital the patient was unconscious, with incontinence of urine. The physical examination was negative except for abrasions on the face, head, and arms. There was slight bleeding from the nose, but no depression of the vault of the skull. The temperature was 100° F.; pulse, 60 to 30. The blood pressure was 215. The attending neurologist, Dr. Cornwall, made the diagnosis of fracture of the base of the skull. There were, however, no focal symptoms, though there was Babinski on both sides, and the patellar reflex was slightly exaggerated. On the following day the patient could be slightly aroused. The blood pressure at 11 A. M. was 240 and at 9 P. M. 190 mm. At night of the following day a hemiplegia developed and there was also paralysis of the right side of the face. The patient could be aroused and when asked to shake hands presented the left hand readily; when asked to move the right hand she lifted it with the left. She could move the left leg, but could not move the right. There was a subconjunctival hemorrhage out of one-half the right eye. Dr. Cornwall advised an immediate operation. The fissure of Roland was outlined on the left side following the Kronlein method of cranial topography. The flap was outlined over this area. The bone was divided with the Hartley-Kenyon electric saw. On turning the flap down it was found that the dura did not pulsate. About four ounces of black clotted blood was found lying on the motor area; this was removed and considerable blood clot was taken from the base. This clot was mixed with disintegrated brain tissue. The exploring finger could easily detect a marked laceration of the brain on the inferior surface of the frontal lobe. The dura was sutured and the skin closed with interrupted silkworm gut. The patient was in excellent condition and regained consciousness during the day. The day following she could move her right arm and leg slightly. She continued to improve, though the incontinence of urine persisted for several days, and finally made a perfect recovery.

Fracture and Dislocation of the Sacrum. Rupture of the Third, Fourth, and Fifth Sacral Nerves; Laminectomy; Nerve Root Suture.—Drs. ANTHONY HARRIGAN and JOSEPH BYRNE made this presentation. The patient, a carpenter, 44 years of age, fell 9 feet from a scaffold, striking on a beam and thence 6 feet to the ground. Just after the injury he had power in the limbs, but no control. Ever since the injury he had loss of control of both bladder and rectum, with absence of erections and of sexual desire. Physical examination showed marked kyphotic deformity, with some scoliosis to the right at the base of the sacrum and a depression at the lower end of the spine on the left, the size of a hen's egg. To the right of this was the dislocated coccyx. Dr. Byrne stated that the neurological examination showed no motor defects except the bladder, rectal, and genital disturbances noted. The sensory manifestations were pain and soreness in the right buttock and at times a shooting sensation from the anus to the penis. Sensation for all forms of superficial stimulation was absent over both buttocks, corresponding to the root distribution of the third, fourth, and fifth sacral nerves. Where, however, the stimuli were of such a nature as to reach the deeper structures, that was pressure, touch, compass points, simultaneously and conecutively applied with steady pressure, extremes of heat and cold in prolonged massive applications, then sensibility was preserved even on the area of skin distribution of the third, fourth, and fifth sacral roots on the left, although these roots were found completely severed on that side. The glans penis was insensitive to prick, as was the perineum and scrotum, except on either side bordering the thigh. The bulbocavernosus reflexes were absent on both sides and the anal reflexes were absent on both sides to stimuli applied cephalad of the center of the anus. The diagnosis made was rupture of the third, fourth, and fifth sacral roots on the right side. Since operation repeated examination had shown a marked improvement on the sensory loss, especially over the perineum, scrotum, and penis. The genital function, as well as the control of the bladder and rectum, had returned and were almost normal. In discussing the symptoms in this case, Dr. Byrne said that the motor mechanism of the bladder and rectal sphincters were functioning irregularly before operation. They were in a state of postural tonus (Sherrington), which could be altered at times. There was a loss of sensibility over the skin supplied by the third, fourth, and fifth sacral roots on the left for all forms of superficial stimulation, and the retained sensibility even for critical elements reached the deeper structures. These facts warranted a reconsideration of Head's division of the peripheral nerves into epicritic, protopathic, and deep sets. A truer and more useful division was that of superficial and deep critical and superficial and deep affective systems, the aponeuroses underneath the skin being an important carrier of both central and affective receptors and nerves.

Dr. Harrigan described the operation which he performed in this case, as follows: With the patient in the prone position, under ether narcosis, an incision 7 inches in length was made over the center of the sacrum. This was extended above over the lumbar spine and below to the coccyx. There was a definite kyphosis of the upper part of the sacrum and a dislocation at the right sacroiliac synchondrosis, causing the posterior surface to occupy an inclined plane. With the use of chisel, gouge, and trephine the central canal of the sacrum was opened. In order to establish the identity of the cauda equina which was in doubt a part of the laminæ and the spine of the last lumbar vertebræ was removed. At the point where the cauda equina entered the sacral canal it had suffered a displacement or pushing backward, so that at this point its direction was almost at right angles to that which lay within the lumbar vertebra. This curving and bending backwards of the cauda equina was caused by the displacement and fracture of the sacral vertebra. The cauda equina was completely enmeshed in scar tissue. This was carefully dissected away and the cauda equina freed. A rupture of the third, fourth and fifth sacral nerves on the left side was demonstrated, confirming Dr. Byrne's diagnosis. The distance between the ends of these nerves and the cauda equina, following complete freshening of the ends, measured one-half to three-quarters of an inch. Each nerve was sutured to the central cauda equina with a mattress

suture of plain catgut, "suture à distance." The coccyx, which was completely dislocated from the sacrum, was removed. Further search showed a large plate of bone detached from the anterior surface of the sacrum and pressing against the pyriformis muscle. Between this bone and the sacrum an adventitious bursa had developed. The bursa was dissected away and the piece of bone removed piecemeal. The overlying muscles were sutured with catgut, a small drain was placed in the lower angle of the wound, and the wound closed. Primary union followed. Findings at subsequent *x*-ray examinations were also presented which showed extensive damage to the pelvic portion of the sacrum, and the sacrolumbar angle much increased, so that one would expect considerable interference with the function of the sacroplexus, cauda equina, and nerves.

Tumor of the Corpus Callosum.—Drs. HARRIGAN and BYRNE also presented this report. Dr. Harrigan stated that the patient was a man, 47 years of age, a crucible steel worker, whose general symptoms were headache, choked disc, vomiting, irritability, and failure of memory and concentration. The local symptoms were a right-sided hemiparesis, twitching of the right hand, general slight impairment of sensibility (pressure pain, posture, and passive movements) more marked on the right. Astereogenosis was present, especially on the right side; smell and taste were impaired on the left, and there were hallucinations of taste. The blood, Wassermann, and *x*-ray examinations were negative. A diagnosis was made of subcortical lesion under the left rolandic region, corresponding to the right hand area. Operation was advised and operation performed which was described in detail. An osteoplastic flap turned down over the rolandic region revealed a plaque of pachymeningitis. No tumor or cyst was perceptible to the eye or on palpation. The patient never regained consciousness, developed edema and coma, and died sixteen hours after the operation. Eight hours after death the brain was sectioned vertically by Dr. John H. Larkin, and the sections studied serially. He found a tumor measuring 8 x 6 cm. in the white matter of the left hemisphere, extending from beneath the cortex of the rolandic area down into the corpus callosum and backward into the occipital lobe. The microscopical diagnosis was infiltrating mixed celled sarcoma. The significant points in this case were: (1) The heredity, the parents, brothers, and sisters dying young. There was a history of headaches and insanity in the mother and of tuberculosis in three brothers. (2) The repeated injuries of the head and the convulsions, hysterical in type, appeared years after the injuries. It was possible that the first and second of these injuries might have played a rôle in the development of the neoplasm. (3) Hallucinations of taste, possibly from indirect involvement (pressure) of the uncal and hippocampal regions on the left. (4) Twitching and later paralysis of the right hand, which were the chief localizing signs. (5) The alternating slow and rapid pulse and the Cheyne-Stokes' respiration, both of which fitted well with the increased pressure found at operation. The comparatively low blood pressure represented probably vasomotor exhaustion. (6) In a similar case a primary decompression would probably best meet the indications, leaving more radical measures for a subsequent occasion.

Dr. MARTIN REHLING reported a case somewhat similar to the case of fracture of the sacrum which Dr. Harrigan had described. This occurred in a child, 4 years of age, as the result of falling four stories. The sacrum was split on both sides, but there seemed to be no injury to the sacroiliac synchondrosis. The child made a good recovery.

Dr. HARRIGAN, in closing the discussion, stated that he was of the opinion that a primary decompression might have been of some value. He thought that someone would raise the point in the case of aphasia and hemiplegia as to why decompression had not been performed when the blood pressure was found to be 240 mm. Some years ago in a paper published by Cushing a statement was made that a decompression should be performed in fractures of the base of the skull when the blood pressure reached 210. In this case he had not operated because the consulting neurologist advised against it; also he felt from his own experience in fractures of the base of the skull that non-intervention cured as many cases as decompression. He felt that it was not wise to make the dogmatic statement that when the blood pressure reached a certain point one should always operate. This was brought out by clinical results and observations.

Multiple Ureteral Calculi.—Dr. LEO BUERGER presented this case, a woman who had already been operated on for right ureteral calculus some four years previously. Because of attacks of intense colic and pain in the right lumbar region, radiating into the ureteral region, operation was again performed, five calculi being removed from the lower right ureter. The patient made an uneventful recovery. The case was of unusual interest from the diagnostic standpoint because cystoscopic examination, radiography, and pyelography demonstrated a number of instructive points: (1) The first radiographs of the pelvis showed nothing suggestive of calculi. A second radiograph showed clearly that a clear radiogram was essential for the demonstration of even multiple ureteral calculi, for two distinct shadows were seen in the course of the left ureter in the pelvis, and five distinct shadows in the course of the right ureter, at a point about 6 cm. from the ureteral orifice. (2) Cystoscopic examination showed that the right ureter, which harbored the five shadows, presented no obstruction to the ureteral catheter, and permitted of the collection of a fairly large quantity of purulent urine, the findings indicating a hydro-pyonephrosis on the right side, that was, the side with the five calculi in the ureter. On the left side, in spite of the presence of the two large suggestive shadows, the catheter passed up the ureter without any hindrance, and perfectly normal urine was obtained. On the passage of a shadowgraph catheter in the left ureter, which seemingly passed up for a distance of 20 cm. without obstruction, the radiogram demonstrated that the catheter had ascended to a point about 12 cm. from the ureteral orifice, and had turned back on itself, making a loop, the upper end of which was lying over the middle of the sacroiliac synchondrosis. The shadowgraph catheter did not come into contact with the two suspected shadows. It was clearly evident that in spite of the negative urine, the ureter was enormously dilated, so that it would permit the catheter to make a loop within it, and that the two suspicious shadows were probably in the ureter, although lying at a considerable distance from the shadowgraph catheter. At a subsequent cystoscopy, the injection of thorium clearly demonstrated the size of the left ureter, and showed that the two suspicious shadows were really calculi lying within it. (3) Another instructive feature was demonstrated when a shadow catheter was passed into the right ureter, for the radiogram showed that the catheter passed upward over the sacrum, and then took a sharp turn into the loin, its tip lying over the center of the ilium, way out in the flank. This unusual course of the shadowgraph did not indicate that the ureter had been perforated by the catheter, as was demonstrated at operation, but that the ureter was enormously dilated, being as large as a small intestine.

Vesical, Ureteral, and Renal Tuberculosis.—Dr. BUERGER presented this patient also and the specimen. He stated that the case was interesting because it emphasized how difficult it was to recognize a tuberculous lesion of the kidney, even when the kidney was bisected, and practically the whole of its pelvis brought into view. The patient was admitted to the surgical service of Mt. Sinai Hospital in July, 1917, under the care of the speaker. He presented the usual symptome of tuberculosis of the kidney and bladder, namely, frequency of urination, burning in urination, and nocturia lasting for about six months. Cystoscopic examinations showed the usual lesions of tuberculosis of the bladder, polypoid edema about the right ureter and slight retraction in this region. Both kidneys functionated fairly well, but tubercle bacilli were found only in the specimens obtained from the right kidney. A diagnosis of right renal tuberculosis and vesical tuberculosis was made, and a typical nephrectomy performed. The kidney was but slightly adherent, fairly movable, about normal in size, and with no gross evidence of tuberculous involvement. The ureter was found densely adherent to the posterior parietes, and surrounded by a mass of connective tissue. With some difficulty, a ureter

as thick as a man's little finger was freed for a distance of about six inches, ligated, cut through, and the kidney then removed. On bisection of the kidney which was presented, the only striking lesion that could be viewed with the naked eye was an intense inflammatory process involving the pelvis of the kidney and calyces, by virtue of which the pelvis was thickened to about three times the normal, its surface being granular as though covered by a multitude of miliary tubercles moderately reddened but nowhere showing the lesions of tuberculosis. The small granules appeared much larger than those characteristic of miliary tuberculosis. No miliary tubercles could be seen in the parenchyma nor were there any gross ulcerations of the apices of the papillae. It was not until a multitude of cross sections had been made through some of the hidden portions of the calyces which had not appeared on the bisection of the organ that typical cheesy ulcerative lesions of tuberculosis were found. These involved a calyx without, however, showing any true miliary tubercles. These cheesy lesions the speaker regarded as absolutely characteristic of tuberculosis and believed that when they were present in the kidney pelvis or ureter a diagnosis might be made even without the finding of endothelial and giant cells. From the standpoint of the operator the lessons to be drawn from this case were: that if the cystoscopic picture was that of tuberculosis, if there was retraction of the ureter, if there were more lesions about one ureter than about the other, if tubercle bacilli were recovered from one side with a moderate amount of pus, a normal appearing kidney upon lumbar incision must not be regarded as free of tuberculosis, but should be removed, particularly if the ureter or pelvis was thickened.

An Unusual Case of Renal Hematuria.—Dr. BUERGER presented a third patient, a man, 51 years of age, with a sufficient number of other lesions of the urinary tract to make the diagnosis of the source of hemorrhage quite difficult. He was admitted to Mount Sinai Hospital in August, 1917, with the history that in April, 1916, he had been under observation for three weeks for a very severe hematuria. The hematuria was painless, without increased frequency of urination, urgency, or any evidence of bladder irritability. The hematuria had continued for three weeks previous to his admission to the hospital, during which time he had lost ten pounds in weight. Cystoscopic examination on several occasions demonstrated the presence of a rather extensive cystitis cystica, and blood coming through the right ureteral orifice. An exploratory operation on the right kidney showed that organ somewhat enlarged and there was marked peripyelitis and periureteritis. The pelvis was opened and the interior mucous membrane inspected and found to be the site of an extensive pyelitis cystica, the ureter also being involved as far as it could be seen. The pathologist reported that a specimen of the kidney removed for miroscopical examination showed chronic interstitial inflammation and parenchymatous degeneration. The pelvis of the kidney and the wound were closed; within a few days the bleeding ceased, and the patient was discharged about seventeen days after the operation. The patient was then apparently free from symptoms until August, 1917, when he was admitted to Mount Sinai Hospital with a profuse hematuria. Cystoscopic examination made it evident that the right kidney was bleeding. The bladder was found to be the seat of an extensive cystitis cystica, but this was evidently not the source of the hemorrhage. The speaker concluded that he was dealing with an idiopathic or essential unilateral hematuria and decided upon an exploratory operation. Careful inspection demonstrated that the bleeding came from the kidney itself, which was small and sclerotic. No tumor or calculus was present. The diagnosis, therefore, was chronic nephritis or possibly essential hematuria. Decapsulation was done and the wound closed. Four days after operation the bleeding ceased. The patient was discharged apparently relieved of his symptoms within two weeks.

Dr. MARTIN REHLING said that he had had a case of hematuria in which cystoscopy showed the urine clear on one side and slightly bloody on the other. At operation a fibroma of the kidney was found.

Dr. WILLY MEYER said that he had not heard all of Dr. Buerger's presentation, but he wished to cite a case that emphasized the point that where one found a unilateral descending tuberculosis of the kidney, even though the kidney did not show a serious lesion, that kidney should come out.

Prognosis in Surgery of the Aged.—Dr. FRANK C. YEOMANS read this paper, which was based on a study of 100 cases selected from his operative experience of the four years to August, 1917. The summary of the 100 cases showed that 22 were from 50 to 59 years of age; 49 from 60 to 69 years; 27 from 70 to 79 years, and two were 80 years or over. The average age was 62 years. There were 65 males and 35 females. The anesthetic employed was ether and chloroform in 57 cases; nitrous oxide gas and oxygen in seven, and novocain in 36. Of the series, 88 recovered and 12 died. The operation was imperative in ten of the fatal cases, and elective in two. After analyzing the series in detail, Dr. Yeomans suggested the following five cardinal rules for successful surgery of old people: "(1) A correct diagnosis made by thorough and, if necessary, repeated examinations before operation. (2) A definite plan of operation, executed with the greatest celerity compatible with safety. (3) Rigid asepsis, for the powers of resistance in the aged are limited. (4) Control of hemorrhage by the Esmarch bandage, posture, segregation and division of vessels between clamps, for blood lost is not quickly replenished in old people. (5) Careful handling of tissues. Trauma of tissues results in diminished resistance and favors infection. 'Quickly in and quickly out' is imperative when invading the abdominal cavity and with the least possible evisceration." Furthermore, he emphasized that the body must be conserved by warm covering during the operation and must be protected thereafter, including the avoidance of drafts. The safeguards against shock were a definitely planned operation, short anesthesia, deft technic, "bloodless surgery," and conservation of body heat. The favorable prognostic factors as stated by the author were: (1) Physically the very old represented the survival of the fittest, or, if naturally delicate, they had not undermined their constitution by dissipation or excess. (2) Abstemious habits of eating and drinking and a routine life were accompaniments of advancing years, hence postoperative toxemia and delirium tremens were less frequent complications than in younger people. (3) The general condition of the patient would be of more weight in deciding the operability of a given case than any slight deviation from the normal of a particular organ as the heart, the kidney, or the lung. (4) The selection of the anesthetic suitable to the patient's condition and to the proposed operation would frequently be a more potent factor in the prognosis than the surgical procedure itself. In major operations under general anesthesia the responsibility of the anesthetist was on a par with that of the surgeon. The more frequently local anesthesia or gas and oxygen could be employed, the better the prognosis. (5) In cancer cases the liability to recurrence after radical operation diminished with advancing years and after palliative operations malignant growths were retarded for longer periods than in younger subjects with their more active tissue changes. Dr. Yeomans stated that his experience justified the conclusion that imperative operations must be performed irrespective of the age of the patient and that other things being equal, in elective cases, age per se was not a bar to successful surgery.

Dr. WILLY MEYER said there was no doubt that the past thirty years had brought about a great change in our ideas with reference to operations on the aged. It was rather difficult to draw a line and say when a man should be called aged. Some of the patients in this series were fifty-two years of age; it might be that some would object to calling them aged. He would prefer to draw the line at about seventy years. However, he thought they had all learned that one did not any longer consider the age of the patient as a contraindication to operation unless some chronic disease was present which would actually forbid operation. His personal experience in operations on the aged included a case of suppurative appendicitis in a man 83 years of age who recovered, gangrene of the gallbladder in a man 75 years of age with recovery, prostatectomy in a man of 82 years with recovery, cancer of the breast in

a woman of 73 years with recovery. An important point was that in operating on the aged the administration of the anesthetic should be in the hands of an expert. Personally he feared sudden dilatation of the right ventricle, and he never allowed an old person to be operated on under gas and ether; if it became necessary to administer a general anesthetic there was nothing better in these old people than a few drops of chloroform, perhaps 20 c.c. in an entire operation. Other important points were the necessity for scrupulous asepsis and attention to the aftertreatment. He did not keep elderly patients long in bed and started the first morning after the operation with breathing exercise. He had the patient draw a long breath every hour so as to inflate the lower lobes of the lungs. With attention to these factors there was no reason why years alone should prevent a person from getting the benefit of the modern advances in surgery.

Dr. FENTON B. TURCK said there was one factor in connection with operations in the aged of which he would like to speak and that was shock. He said he had done a great deal of work in reference to the study of shock when he was associated with Dr. Murphy. Dr. Murphy's success with old people was because of his remarkable care in the prevention of shock. In this factor of shock was to be found the whole crux of the matter as it affected the success of operations in old people. By the term shock he did not mean an arterial exhaustion, but a capillary-venous stasis. In shock the first phenomenon observed was the dilatation of the splanchnic capillary veins; they could be seen to dilate the minute the air reached the abdominal cavity. As a result of the loss of heat the splanchnic capillaries and small veins dilated and the fluid passed into the surrounding tissues, and as the dilatation continued the blood corpuscles also passed out into the tissues. In the prevention of this condition heat was the most powerful agent at our disposal. Heat stimulation applied to the stomach and colon brought about a very prompt reaction. To be effective the degree of heat must be above 110°, raised to 120° F., and must be applied directly to the interior of the stomach and colon as he had described in his articles at various times. As a protection against desiccation the rubber dam or rubber sheet should be used to cover the abdominal cavity, with the exception of the site to be operated upon. One could also make use of small rubber bags introduced gently into the abdominal cavity. It would be found that these procedures prevented capillary venous stasis and dilatation. Dr. Meyer had spoken of dilatation of the right ventricle, and it was quite probable that such dilatation was the direct result of venous stasis. It might be briefly stated that the prime factor in the prevention of shock was the application of heat within the abdominal cavity and heat stimulation applied to the feet, for it had been shown that heat applied to the feet directly stimulated the circulation in the splanchnic area.

Dr. YEOMANS, in closing the discussion, said that in regard to the remarks that were made on shock he had not given special consideration to this factor because the cardinal rules for surgery in the aged provided for the prevention of shock. Dr. Meyer had objected to some of these patients being considered as belonging to the old age class. The majority of the operations in this series were performed on patients in the Central and Neurological Hospital on Blackwell's Island and the patients met with there, because of neurological or other complications, were actually much older from the surgical viewpoint than their years indicated. Dr. Yeomans stated that among his private patients he had had no operative mortality in this series; among the hospital cases a number were *in extremis* when they were admitted.

A New Disease—Bradycardia with Edema.—This affection is perhaps the same as has been mentioned in dispatches in the daily press. According to Gerhardt who has seen 21 cases it is *sui generis*. Several cases ended fatally. The symptoms are few and uniform. At first bradycardia and edema set in, followed in time by anemia and asthenia. The first sound of the heart becomes very soft.—*Correspondenz-Blatt für Schweizer Aerzte.*

State Medical Licensing Boards.

STATE BOARD EXAMINATION QUESTIONS.

TEXAS STATE BOARD OF MEDICAL EXAMINERS.

Austin, June 19, 20, 21, 1917.

(*Concluded from page 662.*)

GYNECOLOGY.

1. What laboratory findings would prompt you to defer operating in elective cases?
2. Etiology of irritable urinary bladder.
3. Etiology and prognosis of chorio-epithelioma malignum.
4. How do neglected fibromata uteri render operative procedure hazardous?
5. Describe an operation for chronic inversion of uterus.
6. Discuss the thyroid gland from a gynecological standpoint.
7. Describe an operation for prolapsed (normal) ovaries with the uterus in normal position.
8. Describe an enteroptotic woman.
9. What is hysterotomy?
10. Sixteen hours after pan-hysterectomy no urine is excreted, patient otherwise O.K. What course would you pursue?

PATHOLOGY.

1. What is an aneurysm? Mention the principal causes of aneurysm.
2. Describe the microscopic appearance of the cerebrum in paresis.
3. Describe the micropic appearance of uterine carcinoma and state where it most often occurs.
4. What is a rhabdomyoma? Describe it microscopically.
5. Describe the changes which take place in tuberculous arthritis of the knee-joint.
6. Describe the pathology of glaucoma.
7. What is angina pectoris? Mention its most prominent causes.
8. What do you mean by cardiovascular-renal disease? What are its most prominent symptoms?
9. What important information could you obtain from a differential leucocyte count? Describe a method of performing it.
10. What is pulmonary emphysema? Mention the most frequent causes of this condition.

PHYSICAL DIAGNOSIS.

1. Differentiate floating right kidney from tumor of the gall-bladder.
2. How may acute peritonitis be distinguished from intestinal obstruction?
3. Differentiate mitral stenosis from mitral regurgitation.
4. Differentiate tabes dorsalis, or locomotor ataxia, from the condition known as spastic paraplegia.
5. What is Kernig's sign? Why is it important in diagnosis?
6. State how to test the patellar reflex, or knee jerk. Give its significance and name three diseases in which it is exaggerated and three in which it is absent.
7. Differentiate pulmonary edema from the first stage of pneumonia.
8. How would you test for motor aphasia?
9. Differentiate smallpox from chickenpox.
10. Say how you would distinguish erysipelas from acute eczema; also from the dermatitis of poison-ivy.

SURGERY.

1. Diagnosis of typhoid perforation of the intestine.
2. Diagnosis and surgical treatment of tuberculous peritonitis.
3. Describe in detail the most approved operation for umbilical hernia.
4. Differentiate acute appendicitis from acute pyelitis.
5. Give diagnosis, prognosis, and treatment of sarcoma of testicle.
6. Differentiate between acute and chronic ischiorectal abscess. Surgical treatment of each.

7. Describe in detail a method of testing out the functions of the kidney.

8. Diagnosis and surgical treatment of basal fracture of the skull.

9. Diagnosis and surgical treatment of fracture of the clavicle at middle third.

10. Diagnosis of tuberculosis of knee-joint in the beginning stage.

ANSWERS

GENECOLOGY.

1. *Operation should be deferred* when the hemoglobin estimation is below 40 or 50 per cent.; in cases of renal insufficiency, hemophilia, leucocythemia, diabetes, nephritis.

2. *Etiology of irritable urinary bladder:* Concentrated urine, lithemia, pelvic disease, cystitis, prolapse of urethra, cystocele, neurasthenia, hysteria, the presence of a tampon or pessary in the vagina, hemorrhoids, and sexual irregularities.

3. CHORIOEPITHELIOMA MALIGNUM. *Etiology.* It only occurs during the physiologically active period of life, and is preceded by pregnancy. Hydatidiform moles and abortions may predispose. *Prognosis* is very grave, as this is the most malignant of all tumors.

4. By delaying the operation there is opportunity for all sorts of complications to develop, such as hemorrhage, anemia, pressure upon bladder and ureters, cystitis, hydronephrosis, cardiovascular degenerations, thrombosis, embolism, pressure on intestines; all of these would increase the risk of operation. Further, the growth of the tumor would necessitate a more extensive operation, and the lowered vitality of the patient would further increase the risk.

5. *Operation for chronic inversion of the uterus.* "Küstner devised the following method: (1) a wide transverse incision into Douglas's cul-de-sac; (2) the introduction of the index-finger through this opening into the inversion funnel of the uterus and separation of any adhesions found; (3) a longitudinal incision through the posterior uterine wall in the median line, beginning about 2 cm. below the inverted fundus and ending about 2 cm. above the os externum; (4) reinversion of the uterus by fixing the funnel with the index-finger in Douglas's pouch, and pressing in the fundus with the thumb of the same hand; (5) suture of the uterine incision by deep and superficial sutures passed on the peritoneal surface; (6) closure of Douglas's cul-de-sac with sutures."—(Kelly and Noble.)

6. The *thyroid gland* is associated with the function of the reproductive organs. It enlarges at puberty during menstruation, and during pregnancy. It is more active in the female than in the male, as it is more prone to pathological affections, particularly during the reproductive period of life. Menstruation is normal if the thyroid is physiologically active; deficiency in the thyroid may delay menstruation at puberty. It is said to be excess of the thyroid secretion which inhibits menstruation during pregnancy. Thyroid secretion also accelerates uterine involution and promotes lactation. Removal of the ovaries causes the thyroid to enlarge. Removal of the thyroid causes atrophy of the uterus. Hypersecretion of the thyroid may be accompanied by amenorrhea and sterility. Ovulation may be stimulated by the administration of thyroid extract.—(McIlroy.)

7. In case of prolapsed (normal) ovary, with uterus in normal position, a conservative operation should be done, such as shortening the infundibulopelvic ligament. This is done as follows: "A silk ligature threaded on a small full-curved Hagedorn needle is passed twice through the infundibulopelvic ligament at the outer edge of the ovary and then carried through the peritoneum and underlying structures above the pelvic brim in front of the external iliac artery. The ligated portion of the ligament is then brought in contact with the lateral pelvic wall, and the free ends of the ligature tied. The ovary is thus raised out of the pelvic cavity and held permanently at its normal level in the pelvis." (Ashton's *Gynecology*).

8. Kemp's description of an *enteroptotic person* is: These patients are usually thin and slender; the abdominal walls are generally flaccid. The angle formed by the ensiform, and lower margins of the thorax is sharp (very acute) in the congenital cases, with a long narrow thorax. The form of the patient is angular and the muscles are thin. There is a concavity between the costal arches in the epigastrium from the ensiform to the umbilicus, and in some a vertical median sulcus between the recti muscles wider above than below. In the dorsal position the abdomen may be flattened above and bulge laterally, and when the patient is erect the epigastrium becomes more depressed, while the hypogastric regions from the umbilicus to the symphysis and the pubic region markedly bulge forward and outward.

9. *Hysterotomy* means a surgical incision into the uterus; it is sometimes used as the equivalent of cesarean section; it is also used to denote the enucleation of a fibroid tumor without opening the uterine cavity.

10. "The *treatment* depends largely upon the cause. When the ureter is obstructed the obstruction should be removed just as soon as a diagnosis can be made. In ileus, operative procedure for its relief is usually too late after suppression occurs, although it should be tried. In all cases where there is no obstruction of the ureter the treatment consists in cupping the loins, hot applications, free purging, and sweating with the vapor bath or with pilocarpine. It should not be forgotten that pilocarpine is a treacherous drug and likely to cause edema of the lungs. Diuretin is recommended after the secretion has started. Irrigation of the rectum with hot salt solution by means of a two-way tube is likewise recommended. The method of Murphy of permitting salt solution to run into the rectum drop by drop, averaging a quart every two or three hours, is to be commended highly. Enemata and subcutaneous injections of salt solution are very useful. The treatment of nephritis as a post-operative affection differs only from that usually laid down in so far as it is modified by the wound and other conditions pertaining to the operation." (Kelly and Noble.)

PATHOLOGY.

1. An *aneurysm* is a pulsating sac containing blood and communicating with the lumen of an artery.

Predisposing causes:—atheroma, syphilis, old age, arteritis, alcoholism, male sex.

Exciting causes:—increased blood pressure (which may be due to severe labor, sudden strains, violent exercise, chronic interstitial nephritis); injury to the artery, and embolus.

2. In *paresis*:—"The microscopic changes in the cortex, according to Mendel, as quoted by Folsom, are as follows: 1. Increase of nuclei and new cell-formation are observed, some nuclei small, some large, and with such varying reactions to coloring agents as to suggest dissimilarity of origin. The stellate or "spider" cells are increased in the upper layer of the cortex, where some may be normally found, and extend to lower layers, as is not the case in normal brains; they, too, may be several times the usual size and also push through the white substance to the ependyma of the ventricles. Proliferation of neuroglia or connective tissue, and in time sclerosis of the cortex which involves the medullary substance also in a greater or less degree is common. 2. The larger blood-vessels may or may not be atheromatous; in the capillaries there is an increase of nuclei in the walls, with thickening and hyaloid degeneration. 3. In the nerve-cells, the ganglion-cells, there are granular and fatty degeneration of protoplasm, sclerosis, and atrophy. 4. Atrophy and final disappearance of the nerve-fibers is observed, not limited to the cortex."—(Hughes' *Practice of Medicine.*)

3. "Carcinoma of the uterus is a malignant atypical neoplasm arising from epithelial structures and showing, as a rule, the well marked alveolar arrangement so characteristic of cancer. Since we find two different kinds of epithelia in the uterus we also find carcinomata differing in the types of their cells. The cancers springing from the portio are almost invariably squamous celled carcinomata. The epithelia lining the portio proliferate rapidly, and infiltrate the underlying connective tissue in the form of pegs or columns or pillars of cells. These cells in proliferating vary a good deal in shape, and deviate from the type from which they originally sprang. In the cervix, where

we normally have no squamous, but only cylindrical cells, we likewise find besides columnar celled cancers, squamous epithelial carcinomata. This is probably due not so much to a preceding or coinciding metaplasia of the epithelia, as to a preceding substitution by which the columnar epithelium has been replaced by that of a squamous type. Carcinoma of the corpus consists, as a rule, of epithelia of the columnar type." (Reed's *Gynecology*.) It occurs most frequently in the cervix.

4. A *rhabdomyoma* is a tumor composed of newly formed striped muscle fibers.

Rhabdomyoma. "In these rare tumors striated muscle fibers are the characteristic elements. They very rarely compose a great part of the tumor, but are intermingled with other elements, fibrillar connective tissue, spindle-shaped and spheroidal cells of various forms, which often appear to be incompletely developed muscle cells. They are not infrequently associated with sarcomatous tissue. Blood vessels and sometimes nerves are also present. The muscle fibers differ, as a rule, from normal striated muscle fibers in their arrangement, which is usually quite irregular, and also in size, being in general smaller than normal fibers, although varying greatly. The sarcolemma is either absent or incompletely developed." (Delafield and Prudden's *Pathology*.)

5. *Tuberculous arthritis*. "As a rule, the deposit of tubercle begins at one spot, and only in the later stages is the disease general. In the *synovial membrane* tubercles form, caseate run together, and burst into the joint, so that general infection occurs. In the meantime the synovial membrane has become thickened and the fringes hypertrophied. The synovial membrane is converted into granulation tissue, which spreads over and erodes the cartilage. When the cartilage has been removed by ulceration and necrosis, the disease spreads into the bone and along the periosteum. In the *bone* the disease begins with a deposit, which leads to rarefying osteitis. The tuberculous focus may caseate and form a chronic abscess, or a sequestrum may occur as a result of surrounding sclerosis. It is only when the disease burrows through the articular cartilage that the joint becomes infected." (*Aids to Surgery*.)

6. *Pathology of glaucoma*.—"If there is a rapid rise in tension, the lens is pressed forward, a fact proved by the shallowness of the anterior chamber, and the suspensory ligament is stretched beyond the power of the ciliary muscle to relax it, as is shown in the lessening in the range of accommodation. There are marked circulatory changes in the eye. Pulsation is noticed in the retinal arteries, and the retinal veins are tortuous and swollen from the increased pressure. As the venæ vorticosæ are also squeezed by the intraocular pressure, an excess of blood is discharged through the anterior ciliary veins, which, in consequence, become dilated and tortuous. The cornea becomes cloudy from pressure, and even the acqueous and vitreous participate in this change. From pressure on the ciliary nerves neuralgia is produced, and paralysis of the sphincter pupillæ and anesthesia of the cornea result. By increase in the vitreous the intraocular pressure is raised. The most important diagnostic change is the excavation or cupping of the disc and atrophy of the nerve-fibers. The final result of intraocular tension is active inflammation and swelling of both the internal and external coats of the eye. Naturally, vision is very much reduced."—(Gould and Pyle's *Compend on Eye*.)

7. *Angina pectoris* is a condition characterized by severe paroxysmal pains in the cardiac region, usually extending into the left shoulder and arm, and accompanied by a feeling of constriction of the thorax and with a sense of impending death. *Causes*:—Interference with the nutrition of the heart, such as obstruction of the coronary arteries, atheroma, lesions of the aortic valve, adherent pericardium, excessive enlargement of the heart. It may be associated with diabetes, syphilis, gout, overexertion, great mental excitement. It is sometimes hereditary.

8. *Cardiovascular-renal disease* is a synonym of chronic interstitial nephritis. It is a condition in which there is disease of the cardiovascular system and also of the kidneys. Its most prominent symptoms are:—Increased blood pressure, arteriosclerosis, accentuation of the aortic second sound, and hypertrophy of the heart, especially the left ventricle; dyspnea and palpitation may also be present.

9. From a differential leucocyte count we can learn whether a leucocytosis is physiological or pathological, differentiate the various forms of leucemia, ascertain the presence of eosinophilia, lymphocytosis, and of pus or infections.

Differential Counting.—For satisfactory work a mechanical stage is essential. At least 500 leucocytes should be counted and checked off according to their variety (small mononuclear, large mononuclear, transitional, polynuclear, eosinophile, mast cell). Begin in the lower right-hand corner of the film, and, by turning the thumb-screw, work upward, covering the film carefully, checking off the leucocytes as they appear and are recognized. When the top of the film is reached, move one field to the left and work downward; continue till a sufficient number of corpuscles are counted.

10. *Pulmonary emphysema* is a condition in which the air vesicles of the lung are over-distended. *Causes*:—Prolonged high intraalveolar tension, such as is associated with heavy lifting, chronic bronchitis, playing on wind instruments, glass-blowing, whooping cough.

PHYSICAL DIAGNOSIS.

1. *Floating right kidney* is usually found behind the colon, it can be replaced, there may be no symptoms referable to the kidney, there may be pain which radiates down the ureter, and there may be nausea, chill, vomiting (Dietl's crises) and red blood cells may be found in the urine; the condition is aggravated by the erect posture.

Tumor of the gallbladder is nearer the surface, is continuous with the liver, cannot be replaced into the renal region, moves with the respiratory movements, and is generally accompanied by symptoms associated with liver or gallbladder; posture does influence it.

2. During the first 24 to 36 hours, the following differential points are of value:

	ACUTE PERITONITIS.	ACUTE INTESTINAL OBSTRUCTION.
Rigidity	Uniform and marked.	Not so marked.
Abdominal distention	Gradual	Rapid except in intussusception.
Visible peristalsis	Not present.	Often visible in early hours.
Pulse	Gradual increase in frequency.	Rapid increase in frequency.
Vomiting	Present at first but does not recur until third day.	Incessant from beginning, becoming fecal.
Constipation	Some results from enemata in early hours.	No result except in fecal impaction.

(Eisendrath.)

3. In *mitral regurgitation*, there is a systolic murmur, heard loudest over the apex, and transmitted round to the left axilla and under the left scapula; the murmur is soft and blowing.

In *mitral stenosis*, there is a presystolic murmur, heard loudest over the apex, and not transmitted; the murmur is generally low-pitched, and rough.

4. In *spastic paraplegia* there is loss of power in both legs, rigidity of both legs, and exaggeration of the deep reflexes.

In *tabes dorsalis*, there is no loss of power in the legs, the knee-jerk is absent, and there will be observed the Argyll-Robertson pupil, lightning pains, ataxic gait, and crises.

5. *Kernig's Sign* consists of an inability to extend the leg completely when the patient is in the recumbent position with the thigh flexed at a right angle with the pelvis. It is of value in the diagnosis of meningitis.

6. The *knee-jerk* or *patellar reflex* is produced by striking the tendon of the quadriceps extensor muscle between the patella and its insertion while the patient crosses the leg loosely over the opposite knee or allows it to hang, relaxed, over the forearm of the examiner.

Simultaneous muscular effort on the part of the patient will serve to increase the reflex. The knee-jerk is *increased* in lateral sclerosis, disseminated sclerosis, incomplete lesions of the cord above the lumbar segment, irritability of the spinal cord such as occurs in spinal meningitis, strychnine poisoning, hysteria, etc., and in some cases of organic cerebral disease. It is *diminished or absent* in locomotor ataxia, neuritis, pseudo-muscular hypertrophy, poliomyelitis, myelitis, and in poisoning by spinal depressant drugs. Pronounced physical exhaustion also serves to lessen the tendon reflexes.

7. In the *first stage of lobar pneumonia* there will be found fever, chills, and crepitant rales. In *pulmonary edema* there is no fever, there are moist rales of all sorts, and bronchial breathing is present.

8. In motor aphasia the patient cannot express himself by spoken language. He should be tested as to voluntary speech, power of repeating what is said to him, reading aloud, voluntary writing, writing what is said to him, copying; he should be tested further as to his ability to understand what is said and what is written.

9. *Smallpox and chickenpox*: (1) Very young children are attacked with varicella, whereas variola usually shows itself in adults. (2) Vaccinated children readily take varicella; not so variola, even in the modified form. (3) Children who have had varicella may contract variola, even soon afterward; or the two diseases may co-exist. (4) Varicella is not inoculable, whereas variola is notoriously so. (5) The eruption of varicella appears in twenty-four hours; that of variola not till the third day. (6) The febrile symptoms continue after the eruption appears in varicella; those of variola subside. (7) In varicella the spots come out in successive crops; this is never seen in variola. (8) The spots in varicella are unilocular, and collapse on being punctured; the spots in variola are multilocular, and do not collapse on being punctured. (9) In varicella the eruption is very irregular, and appears over the body generally; in variola it appears in groups of threes and fives, and is always seen on the limbs. (10) The papule in varicella is soft, and disappears on stretching the skin; in variola it is hard and shotty, and does not disappear on stretching the skin.

10.

Erysipelas	Eczema Erythematosum
1. Sudden onset with chill and marked constitutional symptoms.	1. No constitutional symptoms.
2. Eruption sharply marginated.	2. Fades into surrounding skin.
3. Glazed, shining surface; great edema.	3. Dull, scaly surface; slight infiltration.
4. Color violaceous.	4. Color bright or dull red.
5. Burning pain.	5. Itching more marked.
6. Occurrence of discrete vesicles or blebs.	6. Vesicles occur in patches if at all.
7. Progressive peripheral spreading.	7. Spreading irregular.
8. Runs an acute course.	8. Runs a chronic course.
9. Contagious.	9. Not contagious.

In a typical case of *dermatitis from poison ivy*, the hands, face and genitals become the seat of innumerable closely studded vesicles and blebs, accompanied by redness, swelling, and great burning or itching. The eruption may be carried to various parts of the body by autoinoculation. When the face is involved, the eyelids are greatly swollen and the affection may simulate erysipelas in appearance; the absence of high fever and other systemic symptoms will readily exclude the latter disease.—(From Schamberg's *Diseases of the Skin.*)

SURGERY.

1. *Intestinal perforation in typhoid fever*: Sometimes there is severe, sudden pain localized in the abdomen, and sometimes there is little or no pain. Marked tympanites, great weakness, collapse, anxious look, small, rapid pulse, and difficult breathing are present. The legs are apt to be drawn up, and nausea and vomiting may ensue. Hepatic and splenic dulness disappear, and leucocytosis may be present. The treatment is surgical; laparotomy, with suture of the intestine, should be done as soon as possible. In the meantime opium (or preferably morphine) should be administered.

In case of *intestinal hemorrhage*, blood will be passed by the bowel after an hour or two. In *appendicitis*, there is less collapse at the beginning, and the vomiting is more apt to accompany the pain at the beginning of the attack.

2. Tuberculous peritonitis. *Symptoms:* Poor general health, alternate constipation and diarrhea, abdomen is tender, pain is present in abdomen, wasting is marked, loss of appetite, ascites may be present, enlarged lymphatic glands may be present. *Treatment* is by hygiene and good feeding at first. If this fails, simple laparotomy often cures the ascitic variety, sometimes the fibrous, but seldom the ulcerous. It is not necessary to wash out the abdominal cavity, but only to drain away the fluid and stitch up the opening. Laparotomy may also be required to relieve intestinal obstruction, fecal fistula or localized abscesses.

3. *Operation for radical cure of umbilical hernia.* "(1) Incise at first through skin and fascia only; the incision is elliptical, with upper and lower ends in the median line, and widest part opposite the greatest width of the hernia. (2) Carefully deepen the wound on one side until the abdominal aponeurosis (sheath of the recti) is reached, aiming to come down upon it a short distance to the outer side of the hernial neck. (3) Having once reached the rectal aponeurosis, similarly expose this aponeurosis and the neck of the hernial sac all around the outline of the ellipse. All bleeding is controlled by clamp and ligature. (4) The hernial sac is now incised and its contents dealt with as indicated. Adhesions are separated. Excess of omentum is ligated and excised. All remaining contents of the sac are returned to the abdomen—and kept in place by a large, anchored gauze pad—which is removed just before closure of the abdomen. (5) The entire sac, with the umbilicus and the coverings included in the ellipse, is now excised—dividing the peritoneum in an elliptical manner about the neck of the sac. (6) The peritoneum—or the peritoneum and transversalis fascia together—is sutured with interrupted or continuous gut sutures. (7) The borders of the abdominal ring—formed by the sheaths and margins of the recti muscles—are freshened with curved scissors. The edges of the ring are then brought together with interrupted sutures of kangaroo tendon or chromic gut—using either the plain interrupted suture, or the mattress type. (8) The skin and fascia (unless the fascia be thick enough to require separate gut suturing) are sutured with interrupted silkworm-gut sutures. (9) The part is then well supported by an abdominal dressing."—(Bickham's *Operative Surgery.*)

4. "When the three cardinal symptoms of the disease are present—that is, sudden onset of acute abdominal pain, followed by vomiting, occurring in one previously well; unilateral rigidity of the right lower abdominal wall; tenderness over the site of the appendix—the diagnosis of *acute appendicitis* is warranted in nearly every case. . . . *Pyonephrosis* differs from appendicitis in such marked degree that a diagnosis should seldom be difficult. Its onset is gradual, the pain radiates from the loin to the umbilical region, groin and testicle, and retraction of the latter may occur. Palpation of a tender mass which moves with and is continuous with the kidney is the most reliable sign of abscess of the kidney, while irritability of the bladder and the presence of pus and possibly blood in the urine are important confirmatory signs. In every case where a kidney lesion may be suspected a cystoscopic examination with catheterization of the ureters should be undertaken."—(Deaver's *Appendicitis.*)

5. *Malignant tumors of the testicle* are either sarcoma or carcinoma. They are impossible to distinguish clinically, though in the young only sarcoma occurs. A rapidly-growing tumor, retaining the shape of the testis at first, is found, but soon irregular bosses of unequal consistence, and fluctuating in parts, appear. The disease spreads along the cord, and the lumbar glands are early effected in both. The chance of cure by operation is slight. When the skin of the scrotum becomes infil-

trated the inguinal glands also become enlarged. Death usually occurs in a year from the time the tumor is noticed. *Treatment* consists in early castration.

6. *Acute ischiorectal abscess* is due to infection of the fat of the ischio-rectal fossa with pyogenic organisms. It occasionally results from skin infection, but usually spreads from the rectum. The mucous membrane is abraded by a constipated motion, and the *Bacillus coli* then invades the wall and spreads to the fossa. A fish-bone or pin occasionally causes the wound in the rectum. An abscess forms alongside the rectum, and may burst into the rectum, on the surface, or both, a fistula being likely to follow. *Treatment.*—A free incision should be made at once, opening up every part of the abscess, including the communication with the bowel if it can be found. Cellulitis of a gangrenous type may also occur, and must be promptly treated by free incisions and stimulants.

Chronic ischiorectal abscess is met with in phthisical patients. A caseating focus is found in the fossa, which breaks down and discharges by several sinuses, which may be at a distance from the anus. *Treatment* consists of a free incision, scraping out the tuberculous area, and applying pure carbolic acid.—(*Aids to Surgery.*)

7. The phloridzin test for the functional activity of the kidneys. This consists in the hypodermic injection of five milligrams of phloridzin. This substance is transformed into glucose by the secreting cells of healthy kidneys. If these cells are normal glucose should be found in the urine in from 20 to 30 minutes, and should continue to be excreted for three or four hours. Delayed or prolonged elimination of glucose indicates renal insufficiency.

8. FRACTURE OF BASE OF THE SKULL. The *Signs* are those of (1) injury to the brain, (2) escape of cranial contents, (3) injury of cranial nerves. (1) *Injury to the brain* may be of the nature of concussion, compression, or laceration. (2) *Escape of cranial contents*, which may be blood, cerebrospinal fluid, or rarely brain itself. 1. *Hemorrhage* manifests itself in various situations, according to the position of the fracture. In the *anterior fossa* the bleeding may be from the nose or into the orbit, or may pass back into the pharynx, be swallowed, and subsequently vomited. The eye may be pushed forward and pulsate if the cavernous sinus be ruptured. In the *middle fossa* blood usually runs from the ears; but slight bleeding from the ear may be caused by minor injuries, such as rupture of the membrana tympani, tearing of the lining of the auditory canal, and fracture of the tympanic bone. In the *posterior fossa* a hematoma may form behind the mastoid process. 2. The escape of *cerebrospinal fluid* is a certain sign that a fracture communicates with the subdural space. It may appear in the same situations as hemorrhage, but is usually found escaping from the ear owing to fracture of the petrous bone. The fluid is limpid, specific gravity 1005, with no albumin, but containing pyrocatechin, which gives the same reaction as sugar with Fehling's solution. The amount which escapes may be small or very large, but as a rule it soon ceases. (3) *Injuries to the cranial nerves* vary according to the site of fracture. That most commonly involved is the facial, in the aqueductus Fallopii, and the paralysis may come on immediately from rupture, or after two or three weeks from the pressure of callus.

Treatment. The chief aim of treatment is to prevent sepsis. The ear must be mopped out with an antiseptic, and then kept covered with an antiseptic dressing, as if it were a wound. The patient must then be kept quiet, the bowels opened with a purge, and an icebag applied to the head. The diet should be low, and a return to active life not permitted for six weeks. If septic meningitis occurs the patient is bound to die.—(From *Aids to Surgery.*)

9. *Fracture of clavicle at middle third.* The shoulder, and with it the outer fragment, is depressed, rotated forwards, and drawn inwards. The inner fragment retains its normal position, being held by the rhomboid ligament, so that the outer end of the inner fragment is easily felt under the skin, and appears to be drawn up. The patient usually comes in supporting the elbow on the injured side, and with his head bent over to the side of the fracture to relax the muscles. The displacement is due to the weight of the arm pulling down the outer fragment. *Treatment.*—The displacement must be corrected by drawing the shoulder upwards and backwards and maintaining it in that position by Sayre's method, viz., a broad strip of adhesive plaster is stitched loosely around the middle of the arm, so that the arm can be pulled backwards by it. The plaster is then carried round the back, beneath the opposite axilla, and across the front of the chest, and is finally pinned to itself just beyond the loop for the arm. The loop acts as a fulcrum, so that when the elbow is pushed forwards the shoulder and outer fragment are carried backwards. This position is maintained by a broad piece of plaster, with a hole cut in it for the olecranon, which supports the elbow, and is fastened back and front over the opposite shoulder. The apparatus should be worn for three weeks, and a sling for two weeks more.—(*Aids to Surgery.*)

10. In *tuberculosis of the knee-joint* there are: Swelling at sides of and above patella; joint is semiflexed; skin is edematous; there is a doughy feel round patella; foot is everted; muscles of thigh and calf are wasted; pain is variable; tibia displaced outward and backward, is flexed and externally rotated; the limb shortened; abscesses may form.

BULLETIN OF APPROACHING EXAMINATIONS

STATE	NAME AND ADDRESS OF SECRETARY	PLACE AND DATE OF NEXT EXAMINATION†
Alabama*	W. H. Sanders, Montgomery	Montgomery
Arizona*	J. W. Thomas, Phoenix	Phoenix
Arkansas	T. J. Stout, Brinkley	Little Rock....Nov. 13
California	C. B. Pinkham, Sacramento	Sacramento....Jan. 8
Colorado	David A. Strickler, Empire Building, Denver	Denver....Jan. 1

†Applicants should in every case write to the secretary for all the details regarding the examination in any particular State

Mumps Orchitis Followed by Eunuchoidism.—The old popular fear that mumps in a boy might settle in the testicles and emasculate him is shown to be grounded in fact. In a case reported by Laignel-Levastine and Courbon a young man had a severe case of parotitis with meningeal reaction and double orchitis and developed as sequelæ hypertrophy of the mammæ with atrophy of the penis and testicles.—*La Presse Médicale.*

Miscellany.

Limitation of Biopsy to Frozen Section Methods.—It may be said that the opposition to the use of the exploratory incision for the removal of tissue suspected of malignancy is very real. Many surgeons believe it is never necessary or advisable; others, and they are the majority, believe that in certain situations it is permissible when all other resources of diagnosis (in which should be counted the benefits of consultation) have been exhausted, and even then only (1) when the tumor is a superficial one, or (2) when a frozen section can be obtained immediately and the operation completed under one anesthesia. Under these conditions only can exploratory incision of the tumor tissue be justified.

As a result of the analysis of the replies received a modification of the "Procedure Recommended in the Diagnosis of Early and Suspected Cancer of Different Organs" can be made.

1. Suspected, but doubtful, lesions of the *external skin.* If small, complete excision of the lesion should be performed. If large, excision of a portion of the growing edge of the lesion, followed by cauterization, is to be advised only after all other resources of clinical diagnosis, including consultation, have been employed, and then only when facilities for immediate frozen section diagnosis are available and the operation for cancer, if it prove necessary, can be completed under one anesthesia.

2. Suspected, but doubtful, lesions of the *lip.* If small, V-excision, with a good margin, of the whole lesion, should be performed. If large, excision of a portion of the growing edge of the lesion, followed by cauterization, is to be advised only after all other resources of clinical diagnosis, including consultation, have been employed, and then only when facilities for immediate frozen section diagnosis are available and the operation for cancer, if it prove necessary, can be completed under one anesthesia.

3. Suspected, but doubtful, lesions of the *tongue.* Excision of the whole lesion, if small, should be performed. If large, excision of a portion of the growing edge of the lesion, followed by cauterization, is to be advised only after all other resources of clinical diagnosis, including consultation, have been employed, and then only when facilities for immediate frozen section diagnosis are available and the operation for cancer, if it prove necessary, can be completed under one anesthesia.

4. Suspected, but doubtful, lesions of the *palate,* the *tonsil,* and the *buccal mucous membranes.* If small, excision of the whole lesion should be performed. If large, excision of the margin of the lesion, followed by cauterization, is to be advised only after all other resources of clinical diagnosis, including consultation, have been employed, and then only when facilities for immediate frozen section diagnosis are available and the operation for cancer, if it prove necessary, can be completed under one anesthesia.

5. Suspected, but doubtful, lesions of the *esophagus.* Esophagoscopy and excision of the margin of the lesion may be performed, but the danger of perforation must be borne in mind.

6. Suspected, but doubtful, lesions of the *stomach.* Pylorectomy, gastrectomy or primary gastroenterostomy, to be followed at a later operation, if necessary, by gastrectomy. Here the difference in the severity of the possible operations for benign and for malignant disease is not sufficient to make an exploratory excision into suspected cancer tissue a necessary or advisable preliminary to radical operation.

7. Suspected, but doubtful, lesions of the *small intestine* and *colon.* Excision, with anastomosis. Here the difference in the severity of the possible operations for benign and for malignant disease is not sufficient to make an exploratory incision into suspected cancer tissue a necessary or advisable procedure.

8. Suspected, but doubtful, lesions of the *gall-bladder.* Cholecystectomy. Here the difference in the severity of the possible operations for benign and for malignant disease is not sufficient to make an exploratory incision into suspected cancer tissue a necessary or advisable procedure.

9. Suspected, but doubtful, lesions of the *liver.* If cancer, generally secondary to cancer elsewhere. Exploratory excision, or incision into liver tissue, is rarely necessary or advisable, except to confirm a diagnosis of hopeless malignancy, and thus avoid unnecessary radical operation.

10. Suspected, but doubtful, lesions of the *rectum.* Excision of a portion of the growing edge of the lesion, with cauterization, is to be advised only after all other resources of clinical diagnosis, including consultation, have been employed, and then only when facilities for immediate frozen section diagnosis are available and the operation for cancer, if it prove necessary, can be completed under one anesthesia.

11. Suspected, but doubtful, lesions of the *kidney.* Nephrectomy. Here the difference in the severity of the possible operations for benign and for malignant disease is not sufficient to make an exploratory incision into suspected cancer tissue a necessary or advisable procedure.

12. Suspected, but doubtful, lesions of the *bladder.* Cystoscopy and excision of a portion of the lesion, with cauterization, is to be advised only after all other resources of clinical diagnosis, including consultation, have been employed and then only when facilities for immediate frozen section diagnosis are available and the operation for cancer, if it proves necessary, can be completed under one anesthesia.

13. Suspected, but doubtful, lesion of the prostate. Prostatectomy. Here the difference in the severity of the possible operations for benign and for malignant disease is not sufficient to make an exploratory incision into suspected cancer tissue a necessary or advisable procedure.

14. Suspected, but doubtful, lesions of the *testicle.* Orchidectomy. Here the difference in the severity of the possible operations for benign and for malignant disease is not sufficient to make an exploratory incision into suspected cancer tissue a necessary or advisable procedure.

15. Suspected, but doubtful, lesions of the *cervix of the uterus.* (*a*) Excision of the lesion; (*b*) amputation of the cervix; (*c*) excision of a fragment of tissue, with cauterization. Opinion is not con-

clusive. Some advise hysterectomy on suspicion of malignancy. This is undoubtedly radical, but preserves the patient her best chance of cure. Others prefer the exploratory excision of tissue, or amputation of the cervix, to be followed immediately by the complete operation if frozen section shows cancer.

16. Suspected, but doubtful, lesions of the *fundus of the uterus*. Curettage. Opinion divided. Some advise hysterectomy on suspicion of malignancy. Others advise curettage and immediate frozen section diagnosis.

17. Suspected, but doubtful, lesions of the *ovary*. Oophorectomy. Here the difference in the severity of the possible operations for benign and for malignant disease is not sufficient to make an exploratory incision into suspected cancer tissue a necessary or advisable procedure.

18. Suspected, but doubtful, lesions of the *breast*. Local excision of tumors of the breast suspected of being malignant and submission of the tissue for subsequent pathological report cannot be recommended. If direct incision with frozen section diagnosis is not possible, amputation of the whole breast, with dissection of the axilla, should be performed in suspected cancer in women over thirty-five years of age. This is endorsed by 90 per cent. of the replies.

10. Suspected, but doubtful, lesions of the *lymph nodes* in the *neck*, *axilla* and *groin*, in cases where radical operation is a possibility, even if cancer is found to be present. A block dissection of the area involved, including the adjacent lymph nodes, is to be recommended in preference to the excision of a single suspected node. Where obviously a hopeless case of cancer is shown to be present, removal of a single node may prevent a useless operation and is to be recommended.

20. *Sarcoma* and *obscure tumors* deeply placed. Exploratory removal of tissue for subsequent pathological examination cannot be recommended. Facilities for direct exploration and frozen section diagnosis should be secured in cases where doubts exist after *x*-ray studies and other clinical means of diagnosis are exhausted, before radical operation, such as amputation, is performed.

21. In general, *superficial* and *ulcerated lesions* are the only ones in which fragments of tissue may safely be removed for microscopic diagnosis. In deep tumors, where the exploratory incision necessarily opens up normal tissue to infection, exploratory excision of suspected tissue is to be condemned and should be avoided. Where other resources of diagnosis have been exhausted an exploratory excision, with an immediate frozen section diagnosis, and immediate performance of the radical operation if it prove necessary, is the least dangerous procedure for the patient. *No suspected tissue should be excised for diagnosis, unless by a surgeon who is equipped to perform immediately the radical operation for the cure of cancer of the organ involved* [italics ours].

22. The routine pathological examination of all tumor tissues removed by operation should be made compulsory. To this end, laboratories for the free diagnosis of pathological material should be maintained by the State.—ROBERT B. GREENOUGH, M.D., in *Annals of Surgery*, October, 1917.

Therapeutic Hints.

Scientific Babies.—Herbert B. Wentz states that in his work with children and infants he has tried to carry out the scientific feedings offered by various pediatrists, but his one difficulty has been to find the average baby upon which to demonstrate. After a close study of the young of many species he has found that the desire of the infant is the criterion which governs its early life. So it is with the human baby. No two babies will time their hungry times alike, and no baby will get hungry at like intervals on any two consecutive days. These, he says, are but ordinary observations.

One observation Wentz brings out is that the infants of the animal world do not drink water before they desire it, therefore water should not be forced upon the human infant. He demonstrates this by the training he has given two children, one a girl three and a half years old, who, not having shown a desire for water until she was past six months of age, received nothing but her mother's milk. Likewise, the boy, two years of age, was nearly six months old before he manifested a desire for water, and he, too, during that time subsisted upon his mother's milk. The cutting of their incisors indicated that the alimentary canal was sufficiently developed to digest proteids other than what was contained in their natural food. Upon the cutting of their grinders the starch foods were added, and the appearance of the canines signalized the admission of the full diet. Neither child has had a dose of castor oil or other aid to defecation. They are turned out of doors every day and encouraged to gymnastics. The sleep of these children is sound, and they rise at daybreak.

In the cases where artificial food has been necessary, the food requirements of each particular child has been studied. The digestive habits and alimentary condition of both parents has been ascertained, the Mendelian law making it probable that the chances were even that the child would exhibit in a marked degree its parental proclivities. Excellent results have always been obtained. Weights have been greater than those of the so-called average baby of definite age.

Wentz further states that scientific treatment does not consist in blindly following a textbook outline based on laboratory analyses—the reduction of a multitude of babies to an average baby. An average treatment cannot consistently be successfully applied to the special baby in hand.—*Journal-Lancet*, October, 1917.

WHAT THE AMERICAN SOLDIER NOW FIGHTING IN FRANCE SHOULD KNOW ABOUT TUBERCULOSIS.*

By S. ADOLPHUS KNOPF, M.D., (NEW YORK AND PARIS)

NEW YORK.

CAPTAIN, M. R. C., U. S. ARMY; PROFESSOR OF MEDICINE, DEPARTMENT OF PHTHISIOTHERAPY, AT THE POST-GRADUATE MEDICAL SCHOOL AND HOSPITAL; SENIOR VISITING PHYSICIAN TO THE HEALTH DEPARTMENT'S RIVERSIDE HOSPITAL-SANATORIUM FOR THE CONSUMPTIVE POOR OF THE CITY OF NEW YORK.

WITH AN INTRODUCTION

By WILLIAM H. WELCH, M.D., LL.D.,

BALTIMORE, MD.

DEAN AND PROFESSOR OF PATHOLOGY AT JOHNS-HOPKINS MEDICAL SCHOOL, BALTIMORE; CHAIRMAN OF THE ADVISORY COMMITTEE ON PUBLIC HEALTH TO THE UNITED STATES GOVERNMENT; PRESIDENT OF THE BOARD OF DIRECTORS OF THE ROCKEFELLER INSTITUTE FOR MEDICAL RESEARCH.

MY DEAR DR. KNOPF:—You have added to your many services in the antituberculosis cause by the preparation of your timely brochure "What the American Soldier Now Fighting in France Should Know About Tuberculosis."

I find this article characterized by the same skill, simplicity, and lucidity in presentation and by the same ability in the selection of essential points which have marked your previous publications in this field.

Particularly interesting is your suggestion that our soldiers possessed of such knowledge as you impart and trained in habits of cleanly, healthy living may be missionaries of health as well as comrades in arms to their French colleagues.

Everything possible must be done to protect our soldiers from the risks of tuberculosis, and I believe that the public may be assured that this will be done. Undoubtedly the education of the individual soldier is an important part of these efforts and your pamphlet is an important contribution to this end. There is every reason to anticipate that our army will be spared the pitiful experience of the French in this matter of tuberculosis.

Very sincerely yours,

WILLIAM H. WELCH.

FOREWORD.

Ever since the publication of Prof. Hermann M. Biggs' remarkable article, "Tuberculosis in France," in *The Survey* of May 5, 1917, I have been the recipient of many letters and personal visits from parents and friends of our boys who have gone to France to fight for the liberty and democracy of the world. I have been asked again and again what can be done for our boys so that they may not contract tuberculosis while fighting in France. In the number of *The Survey* just mentioned, Dr. Biggs made the following authoritative statement: "In the beginning of this year it was estimated that about 150,000 French soldiers had been returned to their homes with active tuberculous disease and that more are constantly being discharged for this cause." Besides these 150,000, Dr. Biggs conservatively estimated that there would be altogether, including the civilian population, not far from 500,000 cases of tuberculosis in France to be dealt with, if the war were to terminate at once. This was in January, 1917.

That such statements as these should cause serious anxiety to parents whose sons are now in France, or are about to leave for that country, is easily understood. Yet these parents, as well as their brave boys, should know that the danger of the latter becoming tuberculous is not nearly as great as one might think from the figures quoted.

There was a time in our own country when the frequency of tuberculosis and the deathrate therefrom were as high as it is now said to be in France. It was knowledge of the origin of the disease on the one hand and the methods of cure of the disease on the other which have resulted in a remarkable decrease of tuberculosis throughout the United States. Popular antituberculosis education under the leadership of Dr. Biggs, and the sanatorium movement under the guidance and inspiration of the late Dr. Trudeau, have made the United States rank next to England, the country which has the lowest tuberculosis morbidity and mortality of any of the great countries of the world.

To summarize in as concise and practical a way as possible the ordinary precautions and measures which have helped in the fight against tuberculosis in the United States, as they may be applicable to the lives of our boys in the fields and trenches in France, is the object of this little essay. It is the author's hope that thereby not only may the anxiety of American fathers, mothers, and wives be allayed but that by the example given to their brave French comrades in the methods of living even in trenches, dug-outs, tents, or barracks, or when billeted in the homes of French civilians, our own soldiers may be effective not only in fighting for liberty and democracy, but also in fighting that other great enemy of mankind, known as consumption. Let our American soldiers in the field and also our French brethren in arms know as much as possible about tuberculosis, its causes and prevention, and they will be able to fight this insidious and

*Read before the general session of the American Public Health Association, at its forty-fifth annual meeting in Washington, October 19, 1917. and published by authority of the Surgeon General of the U. S. Army.

invisible enemy as victoriously as they are fighting the visible powers which brought upon the world this indescribable catastrophe.

To make this little essay as practical as possible,

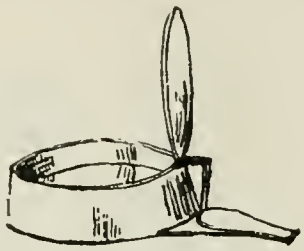

Fig. 1.—Metal floor cuspidor with large opening. Should be partly filled with wet sawdust. Cover worked by the foot.

I will arrange the subject matter in the form of questions and answers.

What is tuberculosis, particularly the most common type known as pulmonary tuberculosis, or consumption? It is the most prevalent of all diseases and is chronic, infectious, communicable, preventable, and curable. All these terms are self-explanatory, except perhaps the word communicable, which the author prefers to the word "contagious." To illustrate the difference between the words "communicable" and "contagious," let us take the two diseases smallpox and consumption, as examples. Smallpox is a highly contagious disease, the word contagious coming from the Latin *contingere*, to touch. No matter how clean or conscientious the smallpox patient may be, no matter how well conducted the smallpox hospital, it is most dangerous to touch the smallpox patient and it is most unsafe to visit a smallpox hospital unless you have been vaccinated and revaccinated recently. On the other hand, the honest and conscientious tuberculous patient, who takes care of his expectoration in the manner which will be described later on, can be associated with and touched without any danger of contracting the disease. The sanitorium or tuberculosis hospital, where all precautions concerning the proper disposal of infectious spittle or expectoration are religiously observed and the patients taught to be conscientious, is the safest place not to contract consumption.

What is the direct cause of tuberculosis? The direct cause of tuberculosis, or consumption, is always the bacillus of tuberculosis, which is a microscopic organism found in the affected parts of the body. Pulmonary tuberculosis, or tuberculosis of the lung, is the type of tuberculosis most frequently found and the type with which those brave French soldiers are now so frequently afflicted; but all other organs of the body (bones, intestines, etc.) can become affected by tuberculosis.

Fig. 2.—The same as shown in Fig. 1, when closed.

Tuberculous disease is locally characterized by countless tubercles, that is to say, small rounded bodies, visible to the naked eye. The bacilli, lodged in these tubercles of which they cause the formation, are parasites belonging to the lowest scale of vegetable life and must be considered as the specific cause of all tuberculous diseases. This parasite, so small that it can only be seen with the aid of a powerful microscope, not only gradually destroys the lung substance through ulcerative processes,

Fig. 3.—Nickelplated oval pocket flask manageable with one hand. Funnel removable.

but at the same time gives off certain poisonous substances called toxins which cause various, and often serious, symptoms. In the secretions or expectorations coming from an affected lung, millions of bacilli can often be found.

What are the early symptoms of pulmonary tuberculosis which can be recognized by the layman? The important earlier symptoms of pulmonary tuberculosis are long-continued cough with or without expectoration, or hoarseness, loss of flesh, flushes or pallor in the face, feverish sensation in the afternoon, occasional night sweats, chilly sensation in the morning, loss of appetite, sometimes a little streak of blood in the expectoration, loss of strength manifesting itself in easy tiring, frequent colds, a perceptible quickening of the heartbeats after slight exertion, a little change in disposition, such as an increased irritability or a feeling of depression.

What are the methods whereby tuberculosis is communicated from one human being to another,

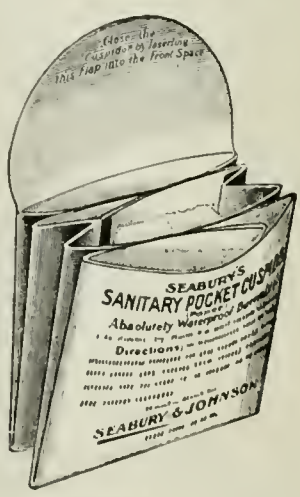

Fig. 4.—Pasteboard sputum purse.

or from animal to man? The three methods by which the germ may enter the human system are by inhalation, ingestion, or inoculation. The tuberculous sputum, when dried and pulverized and mingled with the dust of the air, may be inhaled.

Tuberculous meat or milk taken as food is prone to produce tuberculosis, particularly in children. Inoculation may take place when an open wound or abrasion of the skin comes in contact with tuberculous substance.

Fig. 5.—Pasteboard sputum purse (small size).

How can these methods be prevented or the germs destroyed? The main method of contracting tuberculosis is by inhalation. Whoever coughs and expectorates, whether it be in the trenches, dug-outs, barracks, armories, or other confined places should endeavor not to deposit the sputum where it has a chance to dry up, unless it be where exposure to direct sunlight will render it harmless. When one coughs, let him always hold his hand before his mouth. He will thereby avoid inhalation infection and also spray or droplet infection if he should happen to be afflicted with tuberculosis, influenza, or even an ordinary cold. By droplet infection is understood that manner of conveying the disease by the spray of small particles (droplets) of infectious saliva during the so-called dry cough or even sneezing, and in some individuals during excited speaking.

Of course, it is out of the question to speak of the use of spittoons placed on the floor (Figs. 1 and 2), pocket spittoons (Figs. 3, 4, and 5), or even pieces of cloth to be used for expectoration in the trenches, dug-outs, or similar places, but when in ordinary places of human habitation, barracks, tents, armories, or houses of civilians, even if one expectorates only because of a simple cold or influenza, measles, or whooping cough, he should never do so on the floor or anywhere but in some kind of receptacle where he is sure that the contents cannot dry and become pulverized.

Whenever a receptacle is used it should be covered so that flies cannot have access to it and thus carry the germs of the disease on to food or whatever they may alight on. Spittle should be either poured into the water-closet or rendered harmless by some antiseptic fluid (5 per cent. carbolic acid solution); pieces of cloth used to receive sputum should be burned and paper spitcups with their contents should be disposed of in the same way, for it must be remembered that even the germs of ordinary colds may prove quite serious, particularly when inhaled by one whose general health has been undermined by fatigue, privation of sleep, want of food, etc. These precautions with the expectoration should be especially adhered to when the soldiers after leaving the trenches temporarily or permanently, are billetted in peasants' houses in villages or citizens' homes in towns or cities.

Against the danger of tuberculous food in the form of infected milk or meat, sterilizing or boiling the milk and thoroughly cooking or broiling the meat suffice for all practical purposes. To protect oneself against getting tuberculous inoculation from any skin wound or scratch, it is best to let the wound bleed freely so as to wash away any infectious substances and then use a clean piece of cheesecloth or muslin, steeped in hot water or alcohol, and tie up the wound until surgical aid can be obtained.

What protects the healthy individual against contracting tuberculosis? It should be known to all those who fear to contract tuberculosis because they have been in contact with a tuberculous patient and believe they have inhaled some bacilli, that a healthy individual need not fear to become tuberculous unless he is constantly exposed to the inhalation of the germs. In health, when the human system is in good condition, it is provided with many means of defense against the accidental inhalation of bacilli. First of all, there is the mucous membrane of the nose, the secretions of which have what is known as bactericidal, that is to say, germ-killing properties. The upper air passages are lined with very fine hair-like bodies, known as cilia, which, by an upward waving motion, prevent foreign bodies such as dust particles and germs from entering the deeper respiratory tract. Lastly, in the blood itself, the white blood corpuscles are active in destroying the bacteria. Similar powers are also ascribed to the secretions of the stomach. Besides these four sources of defense, there exist probably in most of us in our circulatory system what is known as antibodies, which likewise counteract the invasion of tuberculosis germs. Thus, anyone possessing average good health need not be afraid of becoming tuberculous even though he may from time to time come in contact with a patient who is not overcareful.

In order for tuberculosis to be contracted from the occasional inhalation of tuberculosis germs or

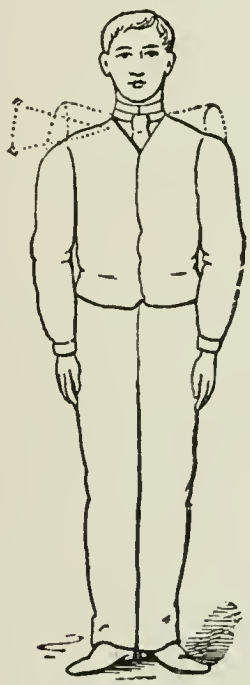

Fig. 6.—Breathing exercise with rolling of shoulders.

even the ingestion of tuberculous food, there must exist the conditions in which the tuberculosis germs can grow; in other words, the subject must be predisposed either by heredity or acquisition. This predisposition may be accounted for by the subject

never having possessed or having lost the power of natural resistance to the germs. When an individual has never been robust and has never possessed the power of natural resistance to tuberculosis, he has probably inherited this predisposition.

What constitutes an hereditary predisposition to tuberculosis? A tuberculous parent, particularly a tuberculous mother, when she has been actively ill with the disease during the time of pregnancy, may transmit to the child such a weakened system that it becomes a ready prey to tuberculosis. If the mother is careless she is sure to infect the child after birth, and because of this early after-birth or post-natal infection tuberculosis is often considered hereditary.

However, for the comfort of those who may have a tuberculous parent let me say here that by reason of the good care bestowed upon him, many such a child has grown up strong and well, and if he has not had tuberculosis by the time he has reached military age, and the disease has not been discovered by the recruiting surgeon, he may safely consider himself free from danger of developing tuberculosis if he leads what might be simply called a normal God-fearing life.

Aside from this hereditary condition, there are, of course, many ways in which a predisposition or loss of natural resistance, producing the ready soil for the growth of the tubercle bacillus, may be acquired.

How is the predisposition to tuberculosis acquired? First of all, there are certain diseases which often leave the system in a weakened condition; among them are measles, whooping cough, typhus and typhoid fever, grippe, chronic bronchitis, pleurisy, pneumonia, also all venereal diseases. Privation, want of food, lack of air and sunlight, insufficient clothing, and the prolonged inhalation of irritating substances, as well as over-fatigue and lack of sleep, may also render the system susceptible to tuberculosis. One of the greatest predisposing causes of tuberculosis is the excessive use and abuse of alcoholic drink. When the alcoholic contracts tuberculosis, the outlook for a cure is most unfavorable. Patients recovering from the above mentioned diseases should be particularly careful to avoid prolonged contact with tuberculous individuals.

What can the soldier in the field do to prevent becoming predisposed to tuberculosis? Since one of the greatest predisposing causes to tuberculosis is alcohol, it is, of course, best for the soldier to abstain etirely from the use of liquor and strong alcoholic drinks. As far as possible he should eat regularly, keep his body clean, and rest when he can so as to avoid over-fatigue. He should keep his bowels in good condition and drink plenty of good, pure water. He should also try to clean his teeth after meals whenever this is feasible. When his garments have become wet from rain or snow, he should not lie down and sleep in them if this can possibly be avoided; and he should be equally careful not to lie down on the moist ground without sufficient protection. But, of course, on the firing line and in trenches and dug-outs these precautions cannot often be carried out and one must do the best he can.

If the air in the dug-outs and trenches seems to be vitiated, that is to say, foul and lacking oxygen, whenever circumstances will permit it the soldier should go where the air is pure and take some deep breathing exercises. The simplest one of all is to inhale deeply, raising the shoulders during the act of inhalation, moving them backward and remaining in that position, retaining the air for about 5 or 6 seconds, then exhale a trifle more quickly by moving the shoulders forward and downward. The accompanying illustration (Fig. 6) will help to explain this exercise. Repeat this exercise 6 to 8 times, and, if convenient, repeat it after half an hour or hour.

If the dug-outs and trenches can be ventilated to admit fresh air, this should by all means be done. In tents and barracks and all other sleeping quarters, the soldier should of course make it his business to see that these habitations are always well ventilated. Fresh air by day and by night is the best preventive as well as curative agent against tuberculosis.

What should the soldier do so as not to spread tuberculosis?—The first symptoms of tuberculosis have been described above. With these he should make himself familiar, and if he coughs and expectorates he should gather a specimen of his sputum and take it to the doctor for examination. Until he has seen the doctor he should use all the precautions possible, that is to say, spit in a piece of cloth or in a receptacle which he should empty into the trench latrine, water-closet, or drain. During the cough he should hold the hand before the mouth and should never swallow his expectoration.

If the soldier perceives any of the symptoms described, he need not think at once that he has tuberculosis, but it is his duty as a soldier to report his condition immediately to the surgeon in charge of his company. He will then be carefully examined and proper care taken of him. If the ailment is not tuberculosis, the examination willl demonstrate it; if it is tuberculosis, the early diagnosis and timely treatment will save the individual's life, for let it be known right here that of all the chronic diseases human flesh is heir to none offers so favorable a chance for cure as does pulmonary tuberculosis if discovered early.

Should the American soldier in France greatly fear contracting tuberculosis after what has been said of the frequency of the disease among French soldiers and the French civilian population?—First of all, let us consider that even before the war the deathrate from tuberculosis in France was twice as high as, for example, in New York City; that is to say, while in France three out of every thousand population were due to tuberculosis, in New York there were only one and a half per thousand. Brave and beautiful France had to mobilize a great army and had to do it quickly. The thorough physical examination, so essential for the discovery of tuberculosis, could not be made, and thus many a young man strongly predisposed had to enter the army in defense of his country. While military life even in trenches and dug-outs may be conducive to the increase of strength and vigor in the normal and healthy individual, the stress and strain of the soldier's life in war time, long marches, life in trenches and dug-outs, and the actual work on the firing line, will develop an active tuberculosis in the strongly predisposed, or in those already afflicted

with incipient tuberculosis, often at an alarmingly rapid rate.

This must be the explanation for the great frequency of tuberculosis among the fighting soldiers in France. Although popular education against tuberculosis had been carried on some time before the war, it was not nearly so intensive and far reaching as in the United States. Thus, for example, in the United States we had 30 organizations doing antituberculosis work in 1905. We have now 1,400 different antituberculosis associations and committees. Dr. Biggs tells us: "At the beginning of the war there were in the whole of France only 1,000 sanatorium beds for tuberculosis and these were in private institutions. There were no provisions for the care of advanced cases excepting as they were received in the general wards of the general hospitals." In the United States we have at this time 530 special tuberculosis sanatoria and hospitals with 35,000 beds. Aside from this, we have 450 clinics and dispensaries for the treatment of cases which do not require or are waiting for institutional care. Of open air schools, which are little known in France, we have nearly 1,000. Thus there is in France a great scarcity of sanatorium and hospital accommodations for the tuberculous in the various stages of the disease, with only a small number of tuberculosis clinics available for the treatment of early ambulatory cases.

Aside from the lack of preventive and curative institutions we must mention another factor responsible for the seriousness of the tuberculosis situation at this time in France. With all our love for the French people, and particularly for our French brethren in arms, we must admit that as a whole they are not taught from their childhood the love of fresh air and the use of cold water as invigorating agents as is the average American boy or girl. This is the fault of their tradition, and their prejudice against the use of cold water and fresh and cold air by day and by night must be overcome in order to reduce the frequency of tuberculosis among the French people. Of course, the hardship this war has imposed upon the French civilian population, the deportation of many of them and the sufferings they had to endure during their enforced absence from home, is largely responsible for the fearful increase of tuberculosis among these people.

All the sad conditions which predispose the individual to tuberculosis either by heredity or custom, and those which are acquired by privation, want, lack of food and air, physical and mental suffering, have combined to increase the number of tuberculous individuals throughout France. Fortunately for the American soldier, his early training in the love of fresh air and the use of cold water on his body have made him naturally more resistant to the disease, and to the honor of our military surgeons it must be said that the examinations at the recruiting offices are most thorough so as to weed out those who are strongly predisposed to tuberculosis or already afflicted with the disease in the incipient stage. The examination is repeated after a few months training so as to make sure that no tuberculous invalid is in active service. Yet, the possibility that some of our soldiers may develop tuberculosis must be admitted; but even should this occur, if the American boy now serving under arms in France will remember his obligation to his comrades, to himself, to his country, and to his allies and profit by these few words of advice, he will not be in great danger of the disease and will be well taken care of if he should get it. There are, as already stated, a large number of institutions which will take care of him on his return home. Many public and private sanatoria throughout the United States have offered to take care of any of the American soldiers who may be returned from France as tuberculous invalids. Do not be discouraged even if you should get a tuberculous infection. The disease is nearly always curable in the early stages.

What can the American soldier, now in France, do to help in the fight against tuberculosis?—I have already stated in my short preface that this essay is written not only to protect our American boys, but also in the hope that by example and teaching they may help to combat this disease of the masses among their French comrades as well as among the citizens with whom they may come in contact.*

Most French people and not a few Americans still fear the night air and are too much afraid of drafts as being most dangerous and the cause of catching colds. First of all, the practice of sleeping with the window open at night in winter and summer should be taught by example and by word of mouth or by printed instructions. But this must be done with great tact so as not to offend. These good people should be made to realize that night air is as good as day air and even purer, for as a rule there is less traffic, less commotion, and less dust in the air at night. Drafts are only dangerous to the individual when he has perspired and the pores of his skin are open; at all other times drafts are beneficial since air currents and winds tend to purify the atmosphere. Colds are never contracted from drafts, but are due to infection just as much as tuberculosis, for all grippes and colds are due to certain specific organisms. The germ of the former is known under the name of Pfeiffer bacillus and the latter by the name of bacillus of catarrh.

It is in the closed and badly ventilated room that the ordinary germs of colds, influenza, measles, whooping cough, and sometimes even the germs of pneumonia are spread by persons coughing into the air. We have already alluded to the precautions every individual should take during the act of coughing, no matter whether he thinks he is ill or not. Ordinary colds, grippe, measles, bronchitis, pleurisy, and pneumonia are often the forerunners of tuberculosis, and we should do all we can to prevent them by hygienic methods; we will thus reduce the frequency of tuberculous disease.

To clean the dust from furniture with the feather duster is still a favorite practice in French and in many American homes. It is in reality one of the most unhygienic ways of cleaning. It does not clean but simply causes the dust to settle in another place, and the people who dust as well as the people who live in rooms cleaned by this method are subject to inhaling the dust which in many instances is not free from disease producing germs. The same conditions result from dry sweeping of rooms or corridors. Cleaning furniture with a moist

*A French translation will be available for distribution to their French comrades.

or slightly oily cloth is far more hygienic and more effective, and scattering moistened bits of torn newspaper or sawdust before sweeping prevents the dust rising.

To avoid the possibility of becoming infected or of infecting others you should never kiss any one, especially not a child, on the mouth. The French custom of kissing on the cheek is far more hygienic. Do not swap eating or drinking utensils, and see that they are always thoroughly clean before use.

Any one who has never used a cold water bath and is fearful of not reacting, that is to say, of not getting warm again after its use, can easily become accustomed to this health-giving measure by beginning to take his cold water applications in the morning in the following way: Stand in a tub containing moderately hot water a few inches in depth and have within easy reach a washbasin full of cold water in which a large sponge has been placed. Squeeze out the sponge full of cold water rapidly over the back, holding it at the neck, then in front over the throat, and over each shoulder in such a way that the whole body receives an ablution of cold water. Dry yourself quickly, not necessarily very thoroughly, and return for a few minutes to the bed, which had been covered after leaving it so as to retain the warmth. Reaction is thus absolutely assured. By this method any individual can train himself to the use of a cold ablution, shower bath, douche, or cold plunge.

In most parts of France there is even a prejudice against drinking water. Now it should be distinctly understood that next to fresh air there is perhaps no greater factor in keeping a man well and strong than a plentiful ingestion of pure water. A moderate quantity (about a glassful) with meals and two glasses between meal times is most conducive to good health.

If the American soldier should come in contact with any comrade or man or woman of the civilian population in whom he should recognize as a result of the study of this brochure the symptoms of a tuberculous disease, let him urge his friend to see a physician and institute such precautions as are necessary to avoid the possible conveyance of the disease to others.

In most American communities, every case of tuberculosis is reported to the health department, whence the physician, if he so desires, can obtain literature which will enlighten the patient and his friends as to the best methods of prevention and cure. In the United States there is usually a large corps of trained nurses attached to the health departments for the purpose of visiting the tuberculous poor, teaching them practical hygiene and seeing that the physician's directions for food and medicine can be and are carried out. If the people are too poor to obtain good and nutritious food, special tuberculosis committees attached to charity organization societies help to obtain it.

What are the agencies now at work to help the French soldier who may have contracted tuberculosis? The Rockefeller Foundation has sent a tuberculosis commission to France composed of expert diagnosticians, sanitarians, and trained nurses under the leadership of Prof. Livingston Farrand, formerly the executive secretary of the National Association for the Study and Prevention of Tuberculosis, and Dr. James Alexander Miller, director of the tuberculosis service of Bellevue Hospital, New York City. In cooperation with the American Red Cross and the French authorities they will foster an educational campaign and establish tuberculosis dispensaries, preventoria, sanatoria, special hospitals, and agricultural colonies. In the sanatoria and hospitals the unfortunate French soldiers who have contracted tuberculosis may be taken care of. In these institutions they will not only have an opportunity to recover but will learn by practical demonstration what to do and what not to do to prevent reinfecting themselves or infecting others, and the surest and best way to regain their health and strength and become fit to enter the ranks again. On returning home they will be useful citizens and will teach others by their example what to do so as not to contract and spread tuberculosis.

What may we hope for regarding the tuberculosis problem in all civilized countries after the successful issue of this war of democracy against autocracy? Since tuberculosis is as much a social disease as it is a medical disease, the prospect of combating the social causes will be brighter when militarism and autocracy will have disappeared from civilized countries. The countries which are now the enemies of the Allies will also become democratized and there will be a united Europe as there is now a united America. Social justice for all will then be the maxim and there can be devoted to the betterment of the social conditions of all peoples the countless billions of dollars that now are spent for maintaining fighting armies because one country would not consent to disarmament, but wished to dominate the world by brute force and uphold the maxim that might makes right. Medical science will then once more be able to devote all its energy to the prevention of diseases. All other branches of science, now utilized in the practice of war, will likewise be consecrated to the betterment and advancement of human happiness, comfort, health, and the enjoyment of life, and with these blessings attained the disease which has justly been called the great white plague, one of the geatest enemies of mankind, will disappear. Thus in the end the sacrifices of life, property, and treasures beyond price made by millions of brave men, women, and even children, will surely lead to a higher civilization where lasting peace on earth and good will toward all men will reign supreme.

CLOUDY ENGLISH AND CHOLECYSTOSTOMY

By Douglas H. Stewart, M.D.

New York.

Professor Henry Johnson once said that for years he had been teaching his students that the cloudiest English often arises from what should be its highest sources. Cholecystostomy is a time-honored operation, the value of which is at present belittled. Yet debate itself is caused by the use of inexact English, as that is exemplified by those who should be authoritative writers but are not expressing accurate thought in clear diction. Should this connection between cloudy language and doubtful esteem for the operation not have been noted, any reader may easily convince himself that the two are cognate. Let him but take any modern

work upon operative surgery, let him read aloud a sentence or two stating that a tube of large caliber and also a prolonged drainage should be employed, let him select for his audience any gathering of his medical friends and let him ask them if the portion of the book that is read is not perfectly clear. A unanimous affirmative would be the expected answer. But let him ask what is a large caliber and how long is prolonged drainage; then it becomes apparent that gall-bladder surgery is in its infancy, that the audience is reasoning as an infant would reason and that the language of the selected sentences, so far from being a light on the subject, proves to be kin to that darkness to which Moses called Pharaoh's attention. That any member of such an audience as the one referred to has ever really measured the caliber of the tubes that he may have employed in performing cholecystostomy or has carefully worked out by actual trial the different effects that may result from the use of different sizes of those tubes, is hardly to be expected in view of the trouble involved in the process.

Admitting that the well-known figures running from 8 to 32 represent a guessing leeway of two dozen numbers to indicate the French scale for tubes or the usual number of days of drainage-duration; yet any one or several of them may be selected by haphazard opinions that are founded upon a basis of "no information." The ultimate conclusions would be such that drawing lots might nearer hit the truth. This little essay is a plea for light because in ancient times, when the cloud abode, then stood the people still for a day, a month, a year, or a longer time. The profession was standing still, is now going backward, and is preparing to condemn a valuable expedient, because the performance of an operation too often means that a second or a third operation is its sequel. That this is due to an obscure thought-conveyance by the use of the indefinite terms "large" and "prolonged" needs nothing more than mention for its defense.

A great stumbling-block is the lack of practice. In fact, who in all the world can sit down at any leisure hour and place a few tubes in a gall-bladder; or who can study that placement carefully or can thoroughly test the joints that he has made? Yet an unlimited means of experiment is within reach of anyone who will expend a few cents to obtain a small urinary bladder with its urethra. The butchers and the slaughter houses have an abundant supply of pigs' bladders, a small straw or blowpipe in the urethra serves for inflation and an ordinary ligature closes the urethra and maintains that inflation. Thorough trials of different stitches and of all sorts of details may then be made at one's leisure. In such trials it is readily discovered that to make a tight joint with a number 6 or number 7 catheter is almost impossible. Surface and elasticity are both deficient. If such a joint is tight it has been made so by a tension of ligature that would cause necrosis of living tissue.

In spite of this fact certain surgeons consider the words "large caliber" as synonymous with sizes six to nine, number ten being termed "very large." Three non-medical opinions are:

1. "A tube for drainage may be capillary or several yards in diameter. Large caliber means from 48 to 60 inches."

2. "We would consider that 'large caliber' in surgical drainage tubes might mean one-half inch or more in diameter; but we would be unwilling to fill an order that merely specified 'large caliber.'"

3. "In view of the enormous pressures developed by the explosion of gases a caliber of 1-10 of an inch would be 'large.'"

A tube must be compressible in order that a tightening ligature may meet elastic counter-pressure against the tissues. The happy medium is not sufficient pressure to produce necrosis and enough tight embrace to prevent leakage. Size No. 32 has many good points for purposes of study. For clinical use a larger size is an advantage, a smaller one is a disadvantage. Red rubber is rather better than black, though either may be used. The walls of the black variety of tube are a little too soft which makes short stitching easy and essential. Also this tube collapses under both pressure and bending. Perhaps as good a plan as any is to describe tubing according to internal diameter and to state that ¼ inch is the smallest size that should be employed, that ⅜ inch is ideal, and that ½ inch may be used in a thin adult where the work is fairly accessible. Through the ½ inch tube a catheter may be introduced for purposes of either medication or cleansing and remaining stones pass readily through such a size. Therefore it is probably true that the stone that was not found, and could not be found at the time of operation, remained permanently because it was securely shut up by the use of a tube, the lumen of which was less than a quarter-inch in diameter.

In practising stitches all sorts of methods may be tried until a single most valuable way is selected. The writer suggests making the gall-bladder climb the tube rather than crowding the tube into the gall-bladder. The steps suggested are: (1) Introduction of tube; (2) Purse-string of tube and orifice, with two or three superficial needle sticks into the rubber to keep the tube from slipping; (3) A Gould mattress stitch that shall clear the tube by at least one-quarter of an inch everywhere, on all four sides. Pulling this tight covers the previous stitch perfectly; (4) A purse-string that enters the outer wall of the tube at one or two points; but without penetration to lumen. This stitch when fastened makes the tube secure, gives an air-tight or water-tight joint; a Bartlett pear with its stem would make a schematic representation of the result, to obtain which the gall-bladder need not be attached to the abdominal wall. The usual catch drain of gauze may be fastened to the tube with a couple of turns of catgut.

When a small tube, of less than ¼-inch lumen-diameter, is used the wound may appear fairly well at first but the leakage of an irritant, like bile, will cause a runaway (a square unhealed place two or more inches on a side) around the tube. On the contrary a large tube and a tight joint allow the tissues to retain all their hugging powers, unaffected, changes of dressings are small trouble to the surgeon, and his nurses are not utterly worn out with many replacements of sheets and bedding.

The absence of odor is also a favorable point. If, however, any one should be wedded to the use of a tube that is ⅛ in. or less in diameter he can make it answer by putting a larger tube over, in sword and sheath style. But why bother with it?

Prolonged drainage has a duration that is in direct proportion to consideration for the patient's interest. The longer the better. Tubes fastened with No. 1 catgut are fairly apt to come out about the ninth day. Those fastened with silk at about the thirtieth day. Much depends on the mode and the size of the bites that have been used in the fastening. Sometimes a tube will remain indefinitely, or until removed. If it is explained to a patient, who has already had an operation or two, that the longer the tube drains the less the chance for a return; then if he is allowed to go home with instructions as to personal care for himself, there will be difficulty in persuading that patient to part with his tube.

The ordinary square bottle of the shops is in no way comparable to the French diamond-shaped one for an ambulant patient. It pokes into him, slips around among the bandages and usually has too small a mouth for a drainage receptacle. It is all angles, whereas the diamond shape may be stuck fast to skin or bandage and will lie flat.

The gauze catch drain is removed on the fourth day and the hole left behind it is packed with Bipp, after which it will need no further attention, save reasonable cleanliness. Or it will do fairly well if cleansed with H_2O_2 and then filled with powdered boric acid. The treatment of the gallstone-patient and of his postoperative wound is important; but may well be left for future consideration.

The summary of the matter under consideration is that "large" and "small" are terms that are absurd unless they are precisely defined by measurements.

Unless a tight joint and a large unchokable tube prevail, the wound will run away from the tube.

Large caliber means from one-quarter to one-half inch, internal measurement.

Prolonged drainage means that a tube is left in place until it falls out. This makes "return" rare even when gallstones are overlooked. A small tube or one 3/16 inch or less in lumen-diameter; or a short time drainage (8 days) make such return fairly sure.

A scale of drainage-duration from 1 week to permanency and based on suture material would be formed about in this order: Catgut, tanned catgut, Pagenstecher linen, linen, silk, and silver wire.

PREMATURE OLD AGE.

By J MADISON TAYLOR, M.D.,

PHILADELPHIA, PA.

PROFESSOR OF APPLIED THERAPEUTICS, DEPARTMENT OF MEDICINE, TEMPLE UNIVERSITY.

Some men grow old at fifty or even forty—women less often. The key to many obscure clinical phenomena will be found by reading them in the light of fluctuating stages of development, maturity and decline. Growth and survival values are influenced, often disastrously, by faulty behavior aggravating morbific agencies, but are capable of much amendment. Premature senility is a condition of gravest significance, but too often escapes attention or right interpretation.

The oncoming of old age is marked by a series of changes which follow in more or less regular order. Variations of course occur due to diversities in original make-up, to circumstances, and above all to manner of life. Occasionally adverse circumstances and unfavorable surroundings become so pressing as to bring about signs and insignia of ageing long before the ordinary time. It is particularly important that these should be recognized at the earliest possible moment, since many of them evidence degenerative changes which can be largely checked and repaired; valuable lives are thereby lengthened and restored to usefulness.

Among the structural origins of presenility to which attention is being critically directed by scientific physicians, research workers, and also by the great life insurance organizations, are conditions of the heart, blood vessels, and kidneys. Disorders in this cardiovascular-renal cycle are those which form the weak spots where final giving way occurs in the course of most diseases; what is known as the "terminal phenomena." The causes are receiving such thorough attention that we may soon hope to learn how to limit them satisfactorily.

Among sources recognized as forceful are variations and alterations in the tone of the blood-vessels, notably in the brain whereby areas of that organ exhibit changed actions. A popular impression prevails widely to the effect that we in America are peculiarly liable to premature breakdown that we frequently show the phenomena of presenility. This is not proven although it is well established that we, as a group, subject ourselves more recklessly and prodigally to mental strains, responsibilities and anxieties, than is customary in older countries.

It is more than probable we are becoming adjusted to these hurtful conditions, are learning how to minimize their effects, and will come in time to an equilibrium, a state of stability. Assuredly we may congratulate ourselves on excelling in prodigal energizing. Newspapers deserve the credit of fostering admiration and emulation for men who are "hustlers," "live wires," "human dynamos." If one fails to attain similar qualities, or rather habits, one might as well "fade away," "go be a farmer" or otherwise self-abnegate.

In consequence of this fashion of prodigal energizing, the outcome of intensive, even grandiose affirmations, a multitude of mountebanks of super-energizing arise, becoming exemplars, "the glass of fashion and the mould of form." Often enough they hasten their own elimination by early acquiring conditions of presenility, then "go smash" and "evaporate from the map." Unfortunately too many of our young men imitate these misguided ones and suffer a like fate.

Now let it be clearly understood that the mere process of working hard, intensively, absorbingly, unremittingly, does not *per se* bring about destructive changes. The foundations of presenility, or other phenomena of breaking down under strains are laid by forming erroneous habits or methods of work and of so called "recreation." Unpardonable sins are committed in the name of sensible

gratification, even though the means be no worse than those which can be legitimately included under the term amusement, recreation, or even relaxation.*

Conditions of fierce, frantic competition, breeding as they do envy, hatred, and malice; inviting to indiscretions in act, in amusements, in food, in drink, irregularity in hours of sleep, inadequate forms and kinds of rest and of exercise, form the foundations of and supply favorable conditions for presenility. Hence it comes to pass that when these unfortunates reach early middle age they show the earmarks of overcombustion, disintegration, cellular decline.

Another factor in this retrograde process is frantic efforts to keep up the pace by using diverse misleading remedies for "nerve tire," headaches, disorders of digestion or of sleep, then acquire sundry perverted appetites and false cravings. Hence we may be often dealing (clinically) with "dope habits" as well as with real evidences of early decline.

Here is a sketch of the common psychic indicators of "physiological senility," the insignia of normal old age changes which appear and along with them certain others, in those who consume their tallow dips at both ends of the wick and otherwise abuse their constitutions: The reproductive powers wane; the emotions no longer act or react normally; capabilities of attention fixing and holding, and of memory fail; desire and capacity to carry on sustained effort both mentally and physically diminish; so are initiation, imagination, confidence, and enthusiasm all lowered; so does adaptability to change, to shift the point of view or of attack subside; also command of speech, *i.e.* of marshalling effective phrases and arguments, grows less.

These changes correspond to the normal ebbing of powers shown in the "period of slowest decline," old age. When, however, they begin to appear before fifty they are good evidence that presenility is setting in.

In addition to these phenomena there are many significant ones only to be detected by exact methods employed by experts such as blood and blood-vessel changes, evidences of disorders in the ductless or blood glands. These last may be the only ones to appear except such vague manifestations of the former group as are in themselves not convincing.

In true senescence, normal decline, the outstanding phenomena have to do with degeneration of the ductless gland. Since these glands regulate the effects of self-poisoning, when they fail of their integrity, autointoxication progresses almost unhindered.

A close connection exists between the adrenals and the thyroids in the genesis of old age, in the form of functional interrelationships. The function of the adrenals is to sustain oxidation and metabolism, the fundamental processes of life. In the aged the adrenals become shrunken and correspondingly deficient in function as the oxidizing agent of the hemoglobin.

The asthenia of senescence and also of senility thus finds a normal explanation in the defective supply of adrenal secretion. In the young, atrophy of these glands may produce similar conditions. "It is quite probable," says Sajous, "that centenarians owe their prolonged longevity mainly to integrity of the adrenals." Lorand says: "All hygienic errors, be they of diet or any kind of excess, will bring about their own punishment and premature old age, or a shortened life, will be the result. In fact it is mainly our fault if we become senile at 60 or 70, and die before 90 or 100."

In ordinary men of good physique and self-control, under emotional strain there may be lost equipoise, they may become irascible, impatient under trifling provocation, also introspective, unable to put aside worries; they exhibit abnormal fatiguability of the mind; "brain fag," are indisposed to mental exertion, avoid the effort of exact reasoning. Associations of ideas exhibit weakening; short cuts are made to conclusions; impatience is shown in trying to follow out new channels of thought. Speech becomes colloquial, fewer and simpler words are used; falling back upon the dialectic peculiarities of childhood, or the "patois"; the whole vocabulary narrows. The sufferer grows indisposed to exertion of any kind or when made it is spasmodically or frantically. After unavailing efforts to achieve, disappointment becomes acute and is often pathetic, followed soon by indifference.

While conscious of failing powers the untimely aged may seem strangely resigned or absurdly incensed at the successes of others. Impairment of memory is an early and significant symptom, along with periods of apathy and dullness.

Certain forms of fierce sudden headaches resembling migraine occur in some clear-headed men after unusual or only moderate strain. These give evidence of over-irritability of the brain vessels to the products of fatigue. As has been said, this whole subject of disturbance and susceptibility of the circulatory mechanism is one of especial significance in connection with untimely ageing.

Among the symptoms noted in the presenile are attacks of giddiness coming on with slight changes in posture, as in stooping down or suddenly turning round, or on closing the eyes. On laying the head on a pillow, a sense is felt as of blood flowing swiftly from the front to the back of the head. Also sudden fatigue and drowsiness coming on the latter part of the day, and subsequently at any time, followed by sudden "clearing of the head," and flights of ideas, mild excitements, waking in the early hours, suddenly and completely, with a cloud of dismal forebodings. All the worries of the previous day seem crowding to the foreground; this is also a phenomenon of vascular degeneration and is common in presenile states.

The senescent individual also becomes hypersensitive to the effects of narcotics, to stimulants, or however one chooses to classify tobacco, alcohol, tea, coffee, etc. These, acting as they do largely on the caliber of the blood-vessels, cause a powerful push to the blood and an overflooding of the hypersensitive brain areas. Hence these effects are not so much evil in themselves as inducing states of uncertainty out of all proportion to the amounts or substances taken. Indeed, great caution should then be exercised in the use of drugs, there being some special susceptibilities difficult to learn.

In a maturing person, otherwise of good poise, who exhibits the following states, presenility may

*A young roysterer was warned by a solicitous aunt that he was thus "shortening his days." He replied: "But you have no idea how I lengthen out my nights."

be shrewdly suspected: Atrophic and flabby condition of skin, fluctuations of blood pressure, often too high for age, accompanied by general evidences of arterial rigidity or hardening, small and sluggishly reacting pupils, also traces of arcus senilis. At that stage it is entirely possible to contribute materially to recovery and add not only to length of days but to efficiency and happiness. A balanced ration is of paramount significance.

The chief means for salvation is to impress the need for circumspection upon the subject. The late Prof. Jackson of the University of Pennsylvania, said about himself at the age of 90: "When I broke down in middle age I came to realize I was a four-minute horse trying to do a two-forty gait. Just so soon as I settled down to a five-minute gait I was able to work satisfactorily till the present."

The whole story is one of working within one's capacities as to speed and sustained effort and these may and do alter with age but more with the effects of exhausting agencies which one must be wise enough either to learn for one self or to employ competent experts to teach one. Then obey directions implicitly and consistently.

1504 Pine Street.

EMERGENCY HEAD SURGERY.*

By CHAS. E. DOWMAN, A.B., M.D., F.A.C.S.,

ATLANTA, GA.

Let us suppose that a physician is called to see an individual who has been hit on the head, or who has sustained a serious fall. Perhaps the patient is not rendered unconscious, but is able to walk to his home or to resume his work; yet a few hours later he becomes drowsy and goes into an unconscious state. Perhaps he becomes unconscious immediately upon receiving the injury and shows no tendency to come out of this condition, but rather sinks deeper into a state of coma. Perhaps unconsciousness is only transitory, the patient regaining full consciousness a few minutes after the injury. Perhaps there may be only a slight laceration of the scalp, with or without evidences of brain damage. What will the physician do under these various circumstances? Will he be content with making a purely superficial examination, and leave instructions that he will see the patient the next day; or will he assume the attitude that any injury, however slight it may appear, may have caused serious damage to the underlying brain, and is therefore worthy of the closest scrutiny and study before he is willing to pronounce the condition trivial?

It is difficult to imagine any type of injury which demands more careful observation and clearer surgical judgment. *A correct diagnosis is all important.* The physician must be well informed on the subject of the pathology of increased intracranial pressure. He must inquire most carefully into the character of the accident in each particular case. His examination should consist of frequent observations of the pulse, the respiration, the blood pressure, the reflexes; if possible, the eye grounds, etc. He may even wish to make a spinal puncture and examine the cerebrospinal fluid for blood. If an *x*-ray apparatus is accessible, this examination may assist him in arriving at a definite conclusion.

When the physician arrives at his diagnosis, the next thing is to determine what should be the nature of the treatment. In discussing this phase of the subject, I will endeavor to give the results obtained by some of the best workers in the field of cranial surgery.

The important question to decide in all such head injuries is whether the underlying brain has undergone damage or not; and if so, what line of treatment is best for the individual case under observation. We still hear a good deal about so-called "concussion of the brain." Unfortunately a great many cases in which the brain has undergone definite lesions, are diagnosed as "concussion." Adami, though admitting that in so-called "concussion of the brain" the nature of the lesion is obscure, claims that in some cases minute hemorrhages are noted. According to him, it is probable that the injury in such cases leads to a rupture of the finer capillaries, solution of the continuity of certain nerve paths, and degenerative changes in the fibers and ganglia. It is generally admitted today that the term "concussion of the brain" is to be used only when a definite organic lesion is not found to be present, thus making the condition a purely functional one. To make such a differentiation, the most painstaking and continuous observation of the patient is required. When the brain is undergoing intracranial pressure the physical signs are practically the same, whether the pressure is due to the accumulation of blood from a ruptured middle meningeal artery or to the edema which follows disturbances of the brain tissues themselves.

The vasomotor, the cardioinhibitory, and the respiratory centers are all situated in the floor of the fourth ventricle, and are affected by the anemia which results from severe compression of the brain mass. As soon as the cerebral pressure exceeds the blood pressure, the vasomotor center is stimulated and the blood pressure is raised above the cerebral pressure; the center thus receives fresh blood and again relaxes and the pulse curve falls below the compression curve. Again an anemia is produced and the vasomotor center stimulated; the blood pressure again goes up, and so on. The respiratory center, instead of being stimulated during anemia, is depressed. This causes the well-recognized slowing of respiration which occurs as cerebral pressure is increased. The cardioinhibitory or vagus center is also stimulated by the progressive anemia, giving rise to a slow pulse.

Thus we have in the study of the pulse, the respiration, and the blood pressure most valuable guides toward a correct diagnosis.

Not infrequently following the accident, the signs of shock (which is usually present) overshadow or even prevent the signs of increased intracranial pressure. If the patient survives this acute condition of shock, then the pulse rate gradually descends, the blood pressure rises, and the deep deflexes, often obliterated immediately after the accident, return. These changes in the reflexes are most interesting. Not infrequently when the patient emerges from the condition of shock to enter the so-called "pressure stage," the abdominal reflexes will appear depressed or absent on the side opposite the cerebral lesion.

*Read before the Georgia State Medical Association, April, 1917.

It is most important in all such cases to make careful examination of the eye grounds. It is rarely possible to observe the early stages of choked disc within six hours after the injury. If the shock is slight and the intracranial hemorrhage a fairly rapid one, blurring of the nasal sides of the optic discs may occur. As the intracranial pressure increases, the veins of the retina become engorged, and eventually choked discs will be noticed.

In doubtful cases it may be wise to do a lumbar puncture and obtain enough spinal fluid to examine microscopically for blood. Some information may be gained by noting the pressure of the cerebrospinal fluid when the puncture is done. If there has been severe brain laceration at the time of the injury usually red blood cells will appear in the cerebrospinal fluid. The absence of blood, however, does not necessarily mean that the brain is not undergoing severe pressure, for it is easy to understand how an epidural hemorrhage from a ruptured middle meningeal artery could take place without blood escaping into the cerebrospinal fluid. It must be kept in mind, also, that a spinal puncture is not entirely without danger. Should the pressure in the spinal canal be reduced too rapidly, it is quite possible that the pressure in the brain may cause the medulla to herniate down into the foramen magnum, thus causing a severe disturbance of the vital centers situated in the floor of the fourth ventricle. The result is immediate death. This valuable aid to a diagnosis, however, should not be overlooked, and should certainly be resorted to whenever one is in doubt.

X-ray examinations are of little importance in the treatment or diagnosis of fractures of the skull. In depressed fractures they may be of some help; but in basal fractures and even in linear fractures of the vault, not only is it rare for the line of fracture to be revealed by the *x*-ray, but the treatment is the same whether a fracture is evident or not.

Severe head injuries usually fall into one of the three following classes: (1) those cases in which there is generalized contusion of the brain and its envelopes, with or without fracture; (2) circumscribed depressed fractures, with or without localized injury of the brain or meninges; (3) a combination of the above two types; namely, those cases in which the character of the fracture and its mode of production are exaggerations of the depressed type, although the effects upon the contents of the cranium are of the first type.

Besley, in his analysis of 1,000 cases of fractures of the skull at Cook County Hospital, gives a report of seventy-four cases examined at necropsy. He was convinced that fractures of the base are not produced by a bursting force, but are due to a direct force applied through the articulation of the condyles and atlas. The thinness of the skull in the region of the middle fossa accounts for the frequent fractures at this site. In other words Besley feels justified in the assumption that in a large majority of fractures of the base, the bursting force is not a factor; but that the true mechanism is the counterforce at the condyles producing a fracture by imbending, or that basal fracture is the direct extension of the fracture at the vault. In his opinion fracture of the base is much more frequently associated with fractures of the vault than is commonly supposed. He found them associated in 72.9 per cent. of his cases. Brün, in an analysis of four hundred and seventy cases, found them associated in 70 to 75 per cent.

There is little need for a discussion of simple depressed fracture cases. Here we have as a rule a localized depression, with or without laceration of the overlying structure. The symptoms vary according to the location involved. Frequently there are no symptoms other than those of the localized trauma, especially when the underlying brain is one of the so-called "silent areas." Occasionally, however, one will have symptoms according to involvement by pressure on one or more of the active cortical centers. This was illustrated in one of my own cases where a depressed fracture over the left temporal region caused an aphasia which cleared up immediately after the bone had been raised. I have been in the habit of treating these simple depressed fractures by cutting down on the depressed bone and elevating it, at the same time examining the underlying structures to see if possible whether or not there was any injury to the brain. I do not think that this treatment is necessary in all cases, for one not infrequently sees patients who at one time or another had a depressed fracture and who never developed any untoward symptoms whatsoever, although no operation had been done.

It is the treatment of those cases in which we have definite evidences of an increasing intracranial pressure, that gives rise to many conflicting opinions.

There are some who still follow the teachings of the late Dr. Fenger concerning the management of skull injuries. According to his method, any patient who had been injured sufficiently to be rendered unconscious, was put to bed with an ice pack on his head and kept there for six weeks, regardless of his symptoms. This so-called "palliative treatment" of head injury is still followed by a great many surgeons.

At the Cook County Hospital of Chicago during 1912, there were 130 cases of skull fracture, 72 being recognized as involving the vault and 58 involving the base. A decompression was done only in those cases which showed a depressed fracture. In all cases of fracture of the base of the skull, the so-called "expectant treatment" (as outlined by the late Dr. Fenger) was carried out, except where a depressed fracture involving the vault co-existed with a basal fracture. The mortality on the expectant plan for basal fracture during this year is shown to be 56.9 per cent. Elsberg reports a series of 60 cases of fracture of the skull treated according to the so-called "expectant method." The mortality in this series was 60 per cent. Compared with this might be his series of 22 patients who were operated upon, either a unilateral or bilateral subtemporal decompression being performed. Of this series the mortality was only 22.7 per cent. Cushing's mortality according to the "expectant method" was 60 per cent. while in his series in which decompression was practised, his mortality was not over 13 per cent. In three of the large hospitals of New York, between the years 1900 and 1910, the mortality of all cases of brain injury was from 46 to 68 per cent. In the 1,000 consecutive cases of

fracture of the skull at the Cook County Hospital of Chicago the mortality was 53 per cent. The so-called "expectant treatment" was practiced in practically all these cases.

Thus it is seen that the mortality of brain injuries in adults is very high when these patients are simply put to bed and not treated with operative measures. This high mortality is due chiefly to the fact that the patients are allowed to reach the dangerous stage of medullary compression which is the result of extreme intracranial pressure. There is no question but that oft-repeated and careful examinations should enable one to anticipate this dangerous stage.

There is no one who will contend that a case diagnosed as ruptured middle meningeal artery should not be operated upon. Is it logical that one should be so energetic in relieving the brain of that pressure which is caused by the accumulation of a blood clot, and yet utterly overlook the necessity of relieving the brain of severe pressure caused by hemorrhage within the brain tissue itself or by the edema which is sure to follow the brain injury? Personally, in the final analysis, I fail to find the distinction. The ruptured middle meningeal artery gives rise to pressure which perhaps comes on more rapidly. Nevertheless the edematous, swollen brain may cause just as much damage to nerve fibers and important centers.

An early operation in such cases is advisable, not only as a means of saving the life of the patient but also of lessening the danger of the post-traumatic conditions so commonly the result of fractures of the skull. These neuroses, such as marked depression, irritability, persistent headache, and even epilepsy, are due in the majority of cases to the resulting unrelieved intracranial pressure, often prolonged over a period of several weeks or more. Dudley Allen of Cleveland, several years ago published a paper in which he analyzed a large number of cases of skull injury without penetration of the dura. Most of the patients eventually found their way to an asylum—most of them had subdural irritation. Sharp of New York was able to trace, several years after they had been discharged from the hospital as cured, 34 per cent. of the patients, who had had fractures of the skull and had been treated expectantly. Of these 34 per cent. 67 per cent. were still suffering from the effects of the trauma; that is, they did not enjoy the same good health they had previous to the injury. The most common complaints were headache; fatigue on slight exertion; vertigo; a lessened emotional control usually of the depressed type; irritability; inability to keep employment; and listless lack of interest in things. Many of these individuals were called "good for nothing," "bums," "happy go lucky," etc. Epileptiform attacks were of not infrequent occurrence. I believe the supposition is justifiable that the majority of these late sequelæ were due to the damage to important nerve structures, brought about by the edema from which the brain suffered during the so-called "compression period." Therefore, if by doing well-timed decompressive operations we accomplish nothing more than the prevention of these distressing late symptoms, such operations would certainly be justifiable. But in addition to this, statistics show us that more is accomplished, for operative interference in the hands of experts has brought the mortality from 50 to 60 per cent. down to 13 to 23 per cent.

I do not wish to be misunderstood as advocating operative procedure in all head injuries. If oft-repeated examinations give no evidences of greatly increased intracranial pressure, operation can be safely delayed. However, if symptoms due to pressure from blood or from edema of the brain tissue appear, then the brain should be given room by means of a decompression operation. It is poor surgical judgment to operate on patients having brain injuries, no matter how extreme, if a condition of severe shock is present. If the pulse is above 120 it is advisable to avoid even all examinations not absolutely necessary, and to depend for the time being on the routine palliative treatment. Very often during this period of shock one is unable to elicit any of the signs or symptoms of increasing intracranial pressure. Any operative procedure for the relief of increased pressure should be undertaken while the pulse is descending (at 60 or below), for once it has reached the lowest level of medullary compression the danger of medullary edema is great. If this occurs, the pulse rate begins to rise rapidly; and it is doubtful that a patient ever recovers, whether operated on or not, once the pulse rate has descended to its lowest level and then begun to rise rapidly.

Conservatism, above all, is indicated in fractures of the skull, and one should have definite signs and symptoms of increased intracranial pressure before surgical interference is instituted. If, however, these signs and symptoms are present, one should not hesitate to give the brain room by means of a well-timed and well-placed decompressive operation. No surgeon would allow a plaster cast to remain on a leg where the swelling is so great that there is danger of grangrene. Why then should he allow the brain to be subjected to an analogous pressure? Conservatism, therefore, in my opinion, means careful study and well-timed operative procedures; and *not* superficial, careless observation and the salving of one's conscience with the statement: "Oh, well, he will either die or get well anyway, so put him to bed and we will see what will happen."

Conclusions: 1. In all head injuries most careful and oft-repeated examinations should be made in order to arrive at a correct diagnosis.

2. Concussion of the brain is a purely functional condition and should never be diagnosed when repeated examinations give evidence of organic intracranial disturbance.

3. We have in the study of the pulse, the respiration, and the blood pressure most valuable guides toward a correct diagnosis.

4. Engorged retinal veins and eventual choked disc indicate increased intracranial pressure.

5. When in doubt a lumbar puncture should be done, although the danger of a possible herniation of the medulla down into the foramen magnum should be remembered.

6. The *x*-ray is of little value except in certain depressed fractures.

7. In patients giving evidence of increased intracranial pressure the mortality is very high (50 to 60 per cent.) when the so-called expectant treatment is employed.

8. A large percentage of patients who recover without operation, after having suffered from an unrelieved increased intracranial pressure, become victims of neuroses, such as marked depression, irritability, persistent headaches, epilepsy, etc.

9. Well-timed and well-placed decompressive operations in those cases giving evidence of increased intracranial pressure will lower the mortality from 50 to 60 per cent. down to 13 to 23 per cent.

10. There is reason to believe that such decompressive operations will also prevent to a large extent the distressing late sequelæ.

PROTEIN DISORDERS AND CONVULSIONS.*

By FREDERIC J. FARNELL, M.D.,
PROVIDENCE, R. I.

(From the Pathological Laboratory of Butler Hospital.)

Maudsley once said: "A person does not inherit insanity, but a tendency or predisposition to it; and secondly the tendency is inherited from the stock and not from any particular development of it in the parentage. It is easy to understand that it is not in special outcomes, but in a foundation of a family nature, that we search for the foundation of insanity." Might this not be applied to epilepsy or the "convulsive diathesis," and every case of convulsions be looked upon as a biological problem, and thus bring its study into not only the knowing of what an individual is born with, but also what has happened after birth?

The object of this preliminary report, therefore, is to bring to your attention a group of disorders which have for years past received little direct investigation. Much stress, heretofore, has been laid upon heredity, and as a result the attention has ended there. Undoubtedly, many cases of convulsions do develop upon an inherited tendency, but the actual attack or seizure is very much different from that which one expects to find in true idiopathic epilepsy.

The relation of convulsions to anaphylaxis might be a matter of conjecture, but investigations tend to show that anaphylactic reactions based upon either protein, fat, or carbohydrate cleavage-products do oftentimes result in convulsive seizures which undoubtedly lead to a state which either resembles or is a true epilepsy. It therefore seems proper to discuss the physiological phenomena which may occur in a so-called pre-epileptic state, as noted in a small series of cases observed by the writer.

There are many points and phases of tissue metabolism due to either native or foreign protein products. The writer will attempt briefly to demonstrate a possible interrelation between the action of these toxic cleavage products of protein metabolism and the vegetative nervous system and its allied endocrine group of ductless glands.

In experimental work upon protein poisons, Vaughan used bacteria of various types for his material. In short, bacteria are nucleoproteins or glyconucleoproteins, very complex in their structural make-up, containing a poisonous radicle which is poisonous to the body cell only during its breaking-down process. This parenteral digestion is influenced in rate or progress by the amount of native ferment present, the physical condition, and the presence of fermentative products. The cells of the body at the same time react to these products by developing another ferment, so that interfunctioning is constantly going on, producing either disease or immunity. This immunity is a sensitization, which sensitization is usually a protein.

These proteins, whether native or foreign, soon distribute themselves through the tissues. Let us turn for a moment to Rosenow's idea of elective localization of bacteria in disease of the nervous system. This investigator has shown that bacteria will retain for a long time their peculiar properties which determine their characteristic localization. He has produced experimental endocarditis with the *Streptococcus viridans*, portal thrombosis by use of the diplococcus, and arthritis by using strains of streptococci.

In 1916, he showed that bacteria obtained from teeth sockets and tonsillar crypts, when cultivated, and injected into animals, would produce myositis, neuritis, meningeal and cord-substance disorders. Given these bacteria in the human body (resting probably, or, better, one may call them "bacterial rests," somewhat similar to the resting of the *Spirocheta pallida* of long-standing syphilis), there undoubtedly is a bacterial and tissue metabolism which has its resultant effect upon the human body in throwing off split protein products which give specific tissue reactions.

This constant introduction of split products is followed by the production of antibodies, which are demonstrated in the phenomenon anaphylaxis. The signs of this disorder are many, both local and general. Rashes, edema of the face and ankles, neuralgic pains, joint pains, headaches, local or general edema of the meninges and brain, or both. The severity of the reaction depends upon the amount of protein split products thrown off, the individual characteristics, and so forth. Grysez and Dupuich have observed extensive edema of the meninges and the brain evincing symptoms of pressure and pseudotumor.

May not these symptomatic phenomena of anaphylaxis be due to autonomic irritation, and when occurring in certain types of individuals thus produce more serious disorders? It is a fact that these cases show further signs of a vegetative nervous disorder, as the writer will attempt to demonstrate.

Gay and Southard, as well as Vaughan, have studied the mechanism of anaphylaxis in animals, and describe the same somewhat as follows: "Within a few hours the stage of peripheral irritation occurs, characterized by a sudden appearance of an urticarial or erythematous rash. The lips and tongue become swollen. Oftentimes the back of the hands. The individual becomes apprehensive. Says he cannot breathe, and falls into a state of collapse. In extreme instances there is retching and vomiting." This can plainly be seen not to be a disturbance of the central nervous system, but rather an irritation of the autonomic nervous system, producing a selective vasomotor paralysis. That this is a peripheral autonomic irritation is further proved by the immediate response to atropine.

Coincident with this peripheral vasomotor paraly-

*Presented May 28, 1917, at Annual Meeting of National Association for Study of Epilepsy, held at Skillman, N. J.

sis there is a fall in blood pressure, and yet little change in the pulse rate, but with a more or less general flush or peripheral vessel dilatation. This then easily explains the central nervous system symptoms, such as anemia of the brain, disturbances in respiration, retching, expulsion of urine and feces, great depression, muscular weakness, tonicity, and even convulsions.

How clearly this compares to the condition of "vagotonia" of Eppinger and Hess. These writers describe a vagotonic disposition, and then a clinical entity which may develop upon such a disposition. These individuals have periodic flushings, profuse salivation, gastric and intestinal disorders, mucous colitis, sluggish intestinal peristalsis, bladder disorders, sweatings, etc., conditions which heretofore have been grouped under the heading of neurasthenic symptoms. Here, too, atropine soon clears the symptoms, thus indicating an autonomic irritation, and yet many of these cases will not recover completely until a foreign protein of some form or other is introduced, either by mouth or hypodermatically.

It is not within the scope of this report to refer to the theory of ionization, as it would require much more speculation than has even now been offered for your approval. But it might be stated, before going on with my case reports, that undoubtedly in convulsive disorders there is a bacterial or tissue protein particle or molecule which causes disharmony in the oxidation and reduction processes of the tissues. This may be viewed in the reverse by considering the older methods of treatment in epilepsy, especially in Europe, by adding to their sodium, potassium, or strontium salts which are electropositive, a weak base such as sodium biborate, which is an electronegative salt. Theoretically, this increases the alkalinity of the blood. How often one observes cases of epilepsy in which will develop an acute infectious disease with a high and continuous temperature, during which illness the convulsions will cease and the patient appear quite well? Here, again, fever increases the alkalinity of the blood, and there is a change in the oxidase-reductase radicle. The actual relationship between vagotonia and fever is speculative at this moment, but Stefani and his collaborators regard the vagus nerve as playing the most important part in heat regulation. Meyer and Auer and Lewis not only regard bacterial poisonings as autonomic depressants, but also believe that the reduction of the body proteins by enzymes can cause the same result with temperature increase.

Thus one can see that within the confines of biochemistry there is a broad stretch of dense forest in which one can meddle in the construction of a paper upon this subject of convulsions.

Case 1.—E. S., age 7 years and 2 months at the time of examination in August, 1916.

Family history: Mother, age 30, an extremely nervous and emotional woman who is said to have had an attack of "hysteria." Father, age 35, a temperate storekeeper who has a gastric neurosis and psoriasis. Maternal grandmother, age 60, has had convulsions dating back to the time of her last childbirth, 23 years ago. Maternal grandfather suffers from "hay-fever." Two maternal aunts, both well. One maternal uncle has attacks of "acute indigestion." Paternal grandmother died at 55 years, of pulmonary tuberculosis; she was a "faith healer." Paternal grandfather died at 82 years of age from "senile psychosis"—he had a chronic skin affection all his life. One paternal aunt has a "chronic skin disease."

Personal history: The patient is the oldest of a family of two, the second child, a girl of five years, who is a "bed wetter." The mother was quite well during gestation; the child was full term, labor was sixteen hours in length and somewhat dry as the bag of waters broke in the early hours of labor. Child weighed 10 pounds; perfectly well so far as could be seen. He was breast fed. He had no convulsions or spasms in infancy. Teeth came through without difficulty. He began to walk at one year and talk at 1½ years. He had no sickness of any kind during the first two years. There were no night terrors, he never walked or talked in his sleep, never fell out of bed; there was no blood noted on his pillow in the morning. He ceased to wet the bed at five years of age. He began school at four years of age, has done well and is now in the third grade. Two years ago, in the spring, he was out of school eight weeks with acute tonsilitis, grippe, and rheumatism—his larger joints were swollen and he was a "very sick" boy. He had no convulsions during this illness. His recovery was uneventful, he went back to school and remained well until his present trouble.

Present condition: The first week in June, 1916, began with night terrors; he would yell and screech, sitting up in bed waving his arms, but would answer when spoken to. Family and attending physician thought he had worms, received treatment accordingly. On July 11 he had two attacks of temporary loss of consciousness while watching a parade. In these attacks he would become limp, raise his arms, and stagger. At this time they began to increase, ranging from four to six a day. His nights became quieter. The condition was considered to be indigestion. Treatment was of no avail. The spells gradually increased in number up to twelve a day, at which time he was called an "epileptic" and bromide treatment was commenced. He was brought to Providence and referred by Dr. Nat Gifford to the writer.

To summarize: A neuropathic family with a decided tendency toward autonomic irritability, gastric neuroses, skin disorders, tuberculosis, and late development of convulsions following childbirth. The patient, a well child until the onset of an acute infectious disease, having had no previous epileptic or epileptoid manifestations, suddenly develops a convulsive seizure. The seizures increase from twelve to one hundred and fifty a day so that on Labor Day he had 94 in eight hours.

With this history and a few days observation, during which time it was noted that milk and eggs invariably increased the number of attacks within two hours after ingestion, the writer was led to seek a cause in a disturbance of metabolism. The attacks were sudden, no aura—he simply became lax and then developed the tonic state, rolling his eyes upward, but did not grind his teeth or bite his tongue. Examination of the blood and urine gave negative findings. Fecal examination revealed very large quantities of mucus. The appearance of this mucus in such large quantities suggested "mucous colitis," probably related to vagotonia, an intestinal neurosis with an abnormal secretory activity. At this same time he demonstrated other signs of autonomic irritability—there were excessive nocturnal sweatings, slow pulse, the secretion of large quantities of saliva, and a great increase in urinary output.

The day following Labor Day he had over 100 attacks in twelve hours, and at the same time his face, neck, and scalp became puffy so that by evening his eyes were closed, his lips and tongue were enlarged, and the edema extended down onto the shoulders and chest. This edema showed pitting on pressure. He was more or less dazed during this period. There was also a feeling that the scalp was raised from the aponeurosis for there was a sensation of fluid under the scalp.

This appearance naturally called for lumbar puncture at which tap 60 c.c. of clear fluid under pressure was obtained. The examination of the fluid for cells, bacteria, albumin, globulin, complement deviation, and colloidal precipitation test proved negative in every respect. Lumbar punctures twice daily for the next four days brought the condition back to normal. The af-

fection was regarded as an extensive edema of the meninges with oozing through the emissary channels under the scalp and a disturbance of the circulation of the face and head resembling the condition of anaphylaxis of the skin.

Having thus tentively concluded (1) upon the introduction of an infection, and (2) upon the irritability of the autonomic nervous system as indicated by his mucous colitis, sweatings, salivation, polyuria, etc., it seemed proper to infer that there must be an altered susceptibility of his body cells to proteins. Therefore two lines of treatment were followed, one directed toward the vegetative nervous system and the other toward tissue sensitization. Atropine sulphate 1/300 grain was given every day for eight days. Foreign protein in the form of tuberculin, 30/100ths of a 1/300 Mg. to a c.c. was given every day for fifteen days. September 28, 1916, he had his last spell and continued perfectly well, gaining in weight and color until four weeks ago (May 1, 1917), when he began again with seizures, having had as many as six in twenty-four hours. Protein sensitization is now being given for the second time.

Case II.—R. W., school boy, age 14 (examination February, 1913).

Family history was negative except for the fact that the father of the child was a relative of the family in which Huntington's chorea is so manifest.

Personal history: He is an only child. Birth was normal, no instruments. Bottle fed. He began to walk at eighteen months and talk at two years. At two years of age he had what was called "meningitis," with residuals in the form of muscular weakness and slow physical development. He had chorea at seven years of age, pleurisy and pneumonia at ten years of age, and frequent attacks of tonsilitis. Following each acute infection he appeared more "nervous," but at no time did he have any convulsions or epileptoid manifestations.

Present condition: At the age of eleven years he had a fainting spell while out automobile riding, falling out of the machine and injuring himself. No further attacks occurred until he was fourteen years of age. He began his adolescent period at the age of 13½ years. In January, 1913, he complained of numbness in his legs, pain around the ankles, black spots before the eyes, dizzy spells, headaches, a sensation of wheels going around in his head, and a sick, exhausted, and weak feeling. Finally actual loss of consciousness in the form of petit-mal attacks would begin to occur several times a day.

It is evident that in this case one was dealing with an adolescent boy who was developing seizures epileptoid in type. This led the examiner to feel that the difficulty bore a direct relation to glandular changes and their products upon the nervous system. Forced feeding of thyroid and pancreatin alone cleared the young man of his attacks in two months and for the last four years he has been perfectly free.

The third and last case report is quite different from the two just cited, and is recorded not because of the presence of convulsive seizures, but because the patient has unconscious attacks, periodical in type, and lasting from a few hours to several days.

Case III.—I. W., age 24, a pupil nurse, American. Family history: One can safely say there is no evidence of nervous or mental disease for at least two generations back.

Personal history: The patient was born outside of Boston, seventh in a family of nine. All she can remember is that she had "inflammation of the bowels" when a small child and ptomaine poisoning at the age of fourteen years. Her menstrual periods began at the age of fourteen years, always regular, moderate in flow, whole period lasting five days. Up until she entered puberty she had no headaches, but since then she has had frequent severe headaches, bearing no relation to her periods.

Present condition: In 1913 she began her training as a nurse and continued at the same for two years. In November, 1914, she states: "I was on duty all day until six o'clock and had been working very hard—as well as studying for an examination. I went off duty at six o'clock feeling very tired, but that was all. I went in to take a bath and I felt faint, I had an awful pain in my side. I lay down on the bed and when one of the girls came off duty an hour later she found me on the bed in a faint; she called in some of the other girls, but they could not bring me to. They called the doctor and he worked over me quite a while before he thought he could bring me to. They were sure I was not going to get better—they sent for my people that night. It was eleven weeks before I was able to go home. There was that awful vomiting, almost constantly for the first few days, during which time I was in and out of consciousness. After the first week I felt pretty good. My color, which had been a black-blue, came back, the vomiting stopped, but it was six weeks before they would let me out of bed." Her next spell was three months later. They are sudden in onset with a feeling of weakness for only an hour or two before the actual attack, which is characterized by retching and vomiting, complete muscular relaxation, absolute loss of all superficial and deep reflexes. Her tongue and lips become swollen. Her color becomes a black-blue. She becomes unconscious. These attacks have occurred every two to four weeks since 1915, and between times she complains of a great deal of tiredness, inability to do things, and says she can't get around as quickly as she used to do.

She was seen by the examiner in October, 1916. Three weeks following the initial examination she had an attack and was found in the following condition: She was lying on the bed unconscious, color a bluish-black, puffed lips, large edematous black tongue, finger tips and nails blue. If one moved her she would retch and vomit a greenish-black mucous material containing free lactic and butyric acid and blood. All superficial and deep reflexes were abolished. Pulse was 84. Blood pressure 90, breathing 28 per minute. At that visit nothing was done but the examiner returned in three hours and decided to perform a lumbar puncture, make blood smears and raise her blood pressure. Patient was given 1 c.c. of pituitary extract intravenously and immediately the blood pressure became elevated 20 mm. Lumbar puncture gave a clear fluid under marked pressure (not estimated in mm.), the examination of which showed 90 cells per cm., 85 per cent. polynuclear leucocytes, and increase in globulin and albumin. Wassermann reaction negative. Colloidal gold negative—no reducing bodies. The Wassermann reaction upon blood serum was also negative. Blood smears showed a polynucleosis. Blood count showed a leucocytosis. She did not pass water nor did her bowels move for eighteen hours. The first specimen of urine passed was highly colored and filled with blood cells. No casts or albumin. Tests for urochrome, indican, urobilin, and acetone were all markedly positive, evidently indicating a high degree of acidosis. Smears from the feces showed the presence of blood.

During the months of November, December, and January the attacks diminished in severity, her color did not change to a deep black, they were shorter in duration, lasting only a few hours. During this period she was given foreign protein hypodermatically and thyroid and pancreatin by mouth—about ten intravenous injections of pituitary extract and occasionally calcium lactate. In February her medication was cut and within a few days she had a severe attack.

During her last attack, two weeks ago, colorimetric examination showed her blood to be 35 per cent more dense than normal blood. Clotting was complete in 1½ min. White blood count 16,000. Urea output 38 grams. Acetone, faint trace in urine. Urochrome and urophein markedly increased.

There is much to be done with this case before a definite decision is given, but it is quite a fact, it seems to me, that here, as in the other two cases, we are dealing with protein split products which damage severely the body cell and cause this characteristic reaction, which coincides with the phenomena of autonomic irritability.

In conclusion it should be stated that it is not the desire of the writer to add another type of

epilepsy to the already enormous group, but it is his desire to demonstrate that many individuals with convulsive seizures might be excluded from the class of epilepsies should their biological mechanism be probed and searched; and this is especially so in the case of those individuals who show this irritability of the vagus system.

BUTLER HOSPITAL.

THE MODERN TREATMENT OF SYPHILIS.*

BY COURTNEY W. SHROPSHIRE, M.D.,
AND
CHARLES WATTERSTON, M.D.,
BIRMINGHAM, ALABAMA.

IT would seem that the most important part of the treatment of syphilis, in the light of our present knowledge, would be prophylactic or preventive, consisting in the application to the genitals, especially in the male, of drugs in the form of ointments to destroy the organism that causes the disease, and of the registration and segregation of all prostitutes during the infective period. Measures of this sort, however, require years of missionary work on the part of the members of the medical profession, to prepare the public for the necessary legislation.

Calomel ointment, 30 per cent. (Metchnikoff and Roux), applied to the penis before, and within an hour or two after, sexual intercourse insures against infection. The condom is, in our estimation, of little value for the upper edges roll and pull out the pubic hair and the secretion from the vagina is deposited in this space which is favorable for infection. Within the last year we have had two patients presenting chancres who had used condoms. The lesions were in the pubic hair and the *Spirocheta pallida* was demonstrated in both cases. As a prophylactic for gonorrhea the condom is of service, but our experience leads us to question its value as a preventive in syphilis.

Attempts have been made at various times to prepare a vaccine or a serum that would confer immunity, but all have failed, and as there is no immunity established by an attack of the disease—as shown by reinfection—the probabilities are that future efforts will avail us nothing.

Extragenital chancres represent but a small percentage of the total and their prevention is being accomplished by the fight for individual drinking cups, inspection of school children, and a dissemination of knowledge of the dangers of infection.

We recently saw two extragenital chancres, one on the finger of a dentist, who had scratched his finger on a patient's tooth, and the other on the tonsil of an old lady who had been treated for tonsillitis. When seen, both cases presented a macular rash and both gave positive Wassermann reactions.

Once infection has taken place and the lesions appear on the surface of the body in any form, or on the mucous membrances, the best way to prevent the spread of the disease is by means of an injection of salvarsan, arsenobenzol, or diarsenol, for then within a few hours the *Spirochcta pallida* will disappear from the lesions on the surface of the body and the mucous membranes, and the patient will no longer be a source of danger to those with whom he or she may come in contact.

It is our custom to excise or destroy the initial lesion or chancre in the primary stage of syphilis. If excision is possible it is done just prior to the first injection of salversan or diarsenol, and if excision is not possible because of the location of the sore, it is destroyed with the high frequency spark. It is always better to do this for the indurated scar may be and is in most cases a focus of infection, and if left to heal may break down at a later date with a recurrence of some of the secondary symptoms.

The question of further treatment is now under debate, some maintaining that it is better to wait until the disease has progressed to the stage of the development of immune bodies, showing that the patient's resistance is being raised. Others use mercury and follow this with one of the arsenical preparations, or the arsenical preparation may be first administered and the mercury given at a later date, again they may be given concurrently instead of consecutively. Some use iodide of potassium in the primary and secondary stages, others only in the tertiary.

Waiting for the patient to develop a resistance to syphilis is a bad procedure, for if syphilis is a self-limited disease its course, like that of tuberculosis, is very long and the chances are that the patient will be overcome by the toxemia before immunity is established.

Mercury is slow in its action and very often the disease progresses even under active mercurial treatment; then again, some patients do not tolerate mercury well. Our experience with salvarsan and mercury given concurrently has been unfavorable. The toxicity of both is increased and the beneficial results, because of this toxicity, are lowered. Iodide of potassium is probably an activator for some ferment within the body which acts on tissue such as we find in gumma, therefore we give it in the secondary stage. It is our practice to give six doses of salvarsan or diarsenol, each dose representing three decigrams, at intervals of seven days, and follow this with one of the mercurial preparations.

The mercurial preparations which are used in the treatment of syphilis are classified as those used: (1) by mouth or ingestion: bichloride, protoiodide, blue pill, calomel, gray powder; (2) by fumigation: calomel; (3) by inunction: mercurial ointment; (4) as plaster: calomel; (5) by injection into the veins or muscles: the drugs used intravenously are the soluble salts of mercury, cyanide, bichloride, succinamide, benzoate, sublimate; (6) for intramuscular injection the following insoluble salts are used in addition to the soluble salts listed above: salicylate, gray oil, calomel, mercurial cream, metallic mercury. Of these preparations, I would select either the salicylate for intramuscular injection or the mercurial ointment as an inunction.

The soluble salts are too quickly eliminated, given either intravenously or intramuscularly, and better results are obtained by us with the insoluble salicylate and the inunction.

The contraindications for the use of mercury are intestinal or renal irritation, salivation, or dermatitis, the last named due to the inunction alone.

*Read at the annual meeting of the Chattahoochee Valley Medical and Surgical Association, held at Warm Springs, Ga., July 10-12, 1917.

It is best to put the patient on daily inunctions or the injection of one grain of salicylate of mercury every other day for a period of six weeks following the course of six doses of salvarsan. After the six weeks of mercury, the patient is given another course of salvarsan, consisting of six doses at weekly intervals, to be followed by mercurial treatment for approximately one year.

A Wassermann test is made after each injection of salvarsan, at intervals during the mercurial treatment, and every three months for one year after all treatment is discontinued. If the Wassermann is negative for one year following treatment, the patient is looked upon as being free of the disease.

The spinal fluid should be examined, but a majority of the patients object to the long-continued treatment, and practically all refuse spinal puncture.

There is no difference in the effect of diarsenol and salvarsan, their toxicity and curative effects being practically the same, as in the mode of preparation. We have had no experience with arsenobenzol, but from the literature on the subject should judge that its action is the same as the two above-mentioned drugs.

The secondary stage of syphilis develops with the appearance of the positive Wassermann reaction, though no secondary eruption is present. It is not unusual for a patient to have a very mild secondary eruption, even when no treatment is administered, so it is better to look upon the appearance of the positive Wassermann reaction as a sign of systemic infection.

Treatment of this stage of the disease is practically the same as that of the primary, with the exception of its being more prolonged.

From six to twelve doses of salvarsan followed by a year of mercurial treatment, after the Wassermann reaction becomes negative, should be the rule and in all cases the spinal fluid should be examined before the patient is dismissed. The blood test should then be negative for one year following the treatment.

Treatment of tertiary syphilis requires a great deal of judgment on the part of the attending physician, but as a general rule it may be said that the best results are obtained when the mercury precedes the salvarsan. The patient's general condition should be improved as much as possible, the teeth being given special attention. Next, he or she should be instructed as to how to live, for this is unfortunately one of the things that few of us know how to do. At least eight hours sleep and, if possible, more. One or more bowel movements every twenty-four hours, nourishing food, abstenance from alcoholic drinks, and moderation in the use of tobacco. Iodide of potassium should be given in 15 grain doses throughout the whole treatment.

It is very difficult in some cases to obtain a negative Wassermann, and we have given from twenty to thirty doses of salvarsan, together with mercurial treatment, at times, before this result could be obtained.

These patients, as a rule, stand mercury well, and it should be continued for a year or more, following a negative Wassermann reaction, for if this is not done the symptoms together with the positive Wassermann will return. The spinal puncture is imperative, for the fluid will be found positive to one or more of the tests in a great many cases.

Spinal fluid for examination should be collected in three tubes, the first for the Wassermann test, the second for the globulin test, and the third for a Lange colloidal gold and cell count. The reason that the fluid is collected in three tubes is because the first is likely to contain a few red blood cells, which will not interfere with the Wassermann, the second is also likely to contain a few red cells and is therefore used in the globulin test, and the third is perfectly clear for use with the colloidal gold and the cell count. After puncture the patient should be kept in bed for at least twenty-four hours to prevent puncture headache.

If any one of these tests is found to be positive, spinal treatment should be instituted at once and continued until results are obtained, or until it is evident that further treatment is useless.

Fluids giving a paretic curve will rarely be changed to normal, but will, after treatment, sometimes present a luetic curve. High cell counts return to normal more quickly, and the globulin and Wassermann tests usually run together.

In general it may be said that a spinal infection can be arrested by means of spinal treatment, but it must be remembered that the best results are obtained in early cases and not after pathological processes have advanced to the point of scar tissue formation, but even then the treatment should be carried out faithfully, for brilliant results have been obtained in some cases.

Where gumma of the central nervous system is diagnosed, or in inflammation of the meninges, it is better to give the mercury first and follow this with salvarsan or diarsenol than to give the salvarsan primarily. If quick action is wanted without the congestion of the affected area, which always follows the injection of the arsenical preparations, give several doses of mercury intravenously and follow with the intramuscular injections or the inunctions.

In concluding this paper, we wish to say:

1. The prophylactic treatment is of the utmost importance in syphilis.

2. A dose of salvarsan should be given all patients with lesions on the skin or mucous membranes to destroy the organisms in these lesions, and thereby prevent the spread of the disease.

3. The initial lesion should be removed and the patient treated energetically with salvarsan and mercury consecutively in the primary stage.

4. At least six doses of salvarsan followed by mercury should be given after the Wassermann becomes negative in the secondary and tertiary stage.

5. A positive Wassermann, in the absence of secondary lesions, constitutes the secondary stage of syphilis.

6. An examination of the spinal fluid—Wassermann, globulin cell count, and Lange celloidal test should be made in every case, if possible, before the patient is dismissed.

7. In the event that any of the above tests are positive, the patient should be treated until the fluid returns to normal.

A CASE OF HYDROPHOBIA; ATTEMPTED SPECIFIC MEDICATION.

By OSCAR BERGHAUSEN, M.D.,

CINCINNATI, OHIO.

A boy aged 5 years was admitted to the children's service of the Cincinnati General Hospital on June 28, 1917. The chief complaint was spasms of the throat on attempted drinking of water. Family history: Father is living and well, aged 25 years; mother, living and well, aged 26 years; one brother living and well, aged 2½ years. No history of tuberculosis or syphilis in family. Grandfather died at age of 64, of carcinoma. No history of insanity in family. Uncle of child was bitten by same rabid dog, on the same day, bite inflicted through clothing. Had twenty-one inoculations of Pasteur vaccine, with no unusual symptoms up to this date. Past history: Aged 5 years (born November 6, 1912). No history of measles, pertussis, or pneumonia. Diphtheria at age of 3 years. Chickenpox at age of 4 years. Otherwise was never ill, up to time of present illness. Six weeks ago the patient was bitten by a dog in the left arm, and the pinna of the left ear was torn. Dog was killed same day and the head sent to Columbus, Ohio, for microscopical examination. Injury occurred at 8 A. M. Physician cauterized the wounds at 8.05 A. M. of the same morning. Report from Columbus was positive for rabies, and Pasteur inoculations were instituted within forty-eight hours. In all twenty-four treatments were given. Last treatment was on June 13, 1917 (two weeks ago). There was no ill reaction. Patient had no complaint and took his meals well and slept well. Monday (three weeks ago), the child complained of pain in the abdomen, which started as cramps followed by diarrhea. Tuesday, the patient vomited all day and lost his appetite, refusing almost all food with the exception of small amount of crackers and an occasional sip of water or milk. Mother noticed spasm of throat yesterday, on attempted drinking of water. There have been no retraction of head, convulsions, or rigidity of extremities. Has never complained of headaches, nor has he been startled by any sudden noises or excitement. There has been no unconsciousness. Patient was seen by members of Cincinnati Health Board and advised to go to the General Hospital for further treatment and observation.

Physical examination: Patient, lying quietly in bed, is a fairly nourished, poorly developed, white male, aged 5 years, of pallid appearance and cheerful countenance. The head is well formed. There are no abnormalities about the scalp. The face is pale and without paralysis or twitching. The pupils are somewhat dilated, but respond to light and accommodation. There is no nystagmus nor strabismus. The conjunctivæ are pale. There is no icterus nor injection of the scleræ. No abnormalities about the ears; there is no discharge and the tympanic membranes are intact. Scar 2 cm. in length in midline of pinna of left ear. No discharge from the nose, no obstruction. The tongue is heavily coated, white, and does not deviate when protruded. No tremor. The breath is offensive. The inferior six-year molars are erupting and can be felt beneath the gums, which are hyperemic and painful to the touch. The lower deciduous molars on both sides are carious. The tonsils are inflamed and somewhat enlarged. No herpes about the lips. No rigidity, no retraction, no visible pulsations, no edema, no thyroid enlargement; the cervical lymph nodes are palpable on both sides, but not greatly enlarged. The thorax is of the long, slender type, the musculature is flabby, and the clavicles and ribs are prominent; it is symmetrical with equal expansion and respiratory excursion on both sides. Tactile fremitus equal on both sides. There is no change in percussion note throughout the entire chest; both fronts and sides are clear on auscultation. Posteriorly breath sounds are somewhat harsh at left base, but no rales are to be heard at any point. Heart: Apex impulse at fourth intercostal space, just outside the midclavicular line. Area of relative cardiac dullness at fifth space is 1.5 cm.; (right) 6.0 cm.; (left) no murmurs are audible. The aortic second sound is accentuated. Rhythm is regular; rate is rapid; volume good. Abdomen is retracted. There is no tenderness, no masses are palpable. The spleen cannot be felt. The liver is not enlarged. The inguinal lymph nodes are palpable on both sides. Right arm presents no abnormalities. On the left arm are numerous scars distributed, extending from the deltoid region to the elbow. No abnormalities about the lower extremities; no paralysis, no deformities, no tremors, no contractures. There is congestion at tip of glans penis surrounding the meatus urinarius. Reflexes: no Kernig, no ankle clonus, no Babinsky, no active knee jerk. Uranalysis: cloudy; light amber; 1020; acid to litmus and methyl red; albumin, negative; heavy sediment; urates xxx; sugar negative; blood negative; no casts. Throat culture sent to laboratory for examination for Klebs-Loeffler bacillus.

Treatment: Rest in bed, absolute quiet, elixir lactopepsin, 1 ounce every four hours. Simple enema (to be retained). Sulphate of magnesia given.

June 29, patient has been very restless during the night. Delirious part of the time with picking at bedclothes and irrational talk. Did not recognize mother. No convulsions during the night. This morning temperature is 102.2°; pulse, 112; respiration, 26. Patient seems more comfortable; is cheerful, and has no complaint. Laryngospasm still marked on attempted swallowing. 10 A. M. Patient has just had a convulsion. Nurse reports that child became rigid, head extended, "eyes rolled upward and remained stationary." Left knee was flexed. Convulsion over by the time the resident physician arrived. The duration of the convulsion was about one minute, and it was followed by complete relaxation.

Treatment: Infusion digitalis, oz. 1, every 4 hours; sodium citrate, potassium acetate, each gr. x, every four hours. Custards, cereals, milk, buttermilk, broths, ice-cream, water *ad. lib.* 11 A. M. Spinal puncture by Dr. Bentley. Results: 20 c.c. of clear fluid under slight pressure. Fluid sent to laboratory. 1 P. M. Discontinue infusion digitalis, substituting tr. strophanthus. Chloral hydrate and potassium bromide, per rectum, p. r. n. for restlessness. Leucocytes, 13,400; reds, 6,820,000. Has had two attacks of convulsions this P. M. of short duration (few seconds). During attacks, the patient extends head with rigidity of neck, flexion of both knees, and rotation of eyes, with delirium and irrational conversation. Patient very restless. Temperature, 105° (rectal). Patient died June 30 at 4.10 A. M. Findings: Spinal fluid—2 lymphocytes per c. mm.; colloidal gold curve in normal zone. On June 29, at 9 P. M., 18 c.c. of blood serum obtained from the median vein of the uncle of the child was injected into the spinal canal.

Although we were not permitted to make an autopsy, we felt justified in adhering to our diagnosis of hydrophobia. Tetanus could be safely excluded. The case is reported because of the general interest in the subject, and because a method hitherto untried was employed as a last resort. The writer was not asked to see the patient until about twelve hours before death, and therefore was not in position to employ this new procedure immediately upon admission of the patient to the hospital. Surely the serum of a man who has just completed the Pasteur treatment contains specific immune bodies. Judging by results obtained in the combined intravenous and intraspinous injection of tetanus antitoxin in patients suffering from tetanus at this institution during the past four years, the writer felt justified in employing a specific serum in this case of hydrophobia. He regrets that he is not in position to carry on further experiments along this line in animals; possibly others more fortunately situated can do so.

The writer wishes to express his indebtedness to Dr. James Bentley for the privilege of seeing this patient.

19 West Seventh Street

POINTS ON NITROUS OXIDE.*

By R. G. McGAHEY, M.D.,
BIRMINGHAM, ALA.
ANESTHETIST TO THE BIRMINGHAM INFIRMARY.

It is not the intention of the author of this paper to try to dissuade you to exclude ether and chloroform from the field of general inhalent anesthetics. These two have in the past done yeoman service and must perforce remain, because of their convenient bulk and slight cost, as valued aids in general surgery. But I desire rather to bring to your minds the notable difference in the effect of nitrous oxide-oxygen on your patient, not only at the time of administration, but following the administration of this agent.

The great public from which we take our patients, I call it the comfort-loving public, has awakened to the fact that anesthesia can be produced without the discomforts heretofore endured, and so a large percentage of patients demand gas.

To my opinion, nitrous oxide-oxygen is the anesthetic of choice. Its safety is generally recognized, provided always the administrration is in the hands of an expert. Right at this point, I wish to say, that the old idea of allowing an inexperienced or unskilled attendant to administer any inhalant anesthetic is evidence of thoughtlessness on the part of the surgeon who values good results.

Briefly, I will enumerate some of the properties of nitrous oxide. A gas practically odorless, colorless, with a sweetish taste, non-inflammable, rapid in its action, producing complete anesthesia in from two to five minutes, fleeting in its effect when discontinued, non-irritating to mucous membranes, producing no ill effect upon kidneys, lungs, or heart.

What does the patient gain by these properties? It gives the anesthetist an opportunity to reassure the patient, to relieve the mental anxiety and stress by assuring him that he will not be subjected to discomfort while he is being put to sleep. That his lungs, heart, and kidneys will not be put to an extra strain. That he can confidently expect a safe conduct to anesthesia and following that a quick return to consciousness; which latter is uppermost in the patient's mind.

In a large percentage of cases of administration of nitrous oxide, we see a total lack of struggling and excitement, these two potent interferences with the respiratory rhythm and consequent causes of acidosis nearly always evinced in the other inhalant anesthetics. The tendency to nausea and vomiting is minimized and when present is rarely prolonged. Nausea is most frequently caused by insufficient use of oxygen.

A point that I wish particularly to stress is that no patient should be allowed to become even minutely cyanotic, as even a slight degree of cyanosis over a lengthy period of time produces acidosis with subsequent vomiting, and acid findings in the tissues and urine, acetone or diacetic acid.

Another point of interest is regarding the use of nitrous oxide-oxygen in the very old. These cases, as a rule, require very little mixture and are rapidly anesthetized; all danger of post-operative pneumonia is evaded, rendering them excellent risks.

The author has in mind the case of an old lady, Mrs. ———, seventy-six years of age, presenting for abdominal section. The patient was admitted at 2 A.M., carried to the operating room in a state of considerable shock, a rupture of the appendix being suspected. Pulse 120, temperature 103°, respiration 32, abdomen distended; leucocystosis 17,000; the urinary examination gave albumin plus, the heat test precipitating the albumin until the content of the test tube was a solid mass. The patient was warmed with packs and hot water-bottles, a preliminary injection of morphine, gr. ¼, atropine, gr. 1/150, was given immediately, and she was made as comfortable as possible on the table and reassured that all would be well. Nitrous oxide-oxygen was administered for a period of forty minutes, the appendix was removed, and a drain used. The patient awoke immediately after the operation, was put to bed and placed in the Fowler position for eight hours. Soda and glucose in solution were given by rectum; the patient voided urine without use of catheter, and the albuminous urine cleared up in about seven days. The patient made an uneventful recovery.

If time permitted I could give you histories of many very old patients who have undergone successful operations by the aid of nitrous oxide.

A point that is of interest is that the necessity of catheterization is rare when nitrous oxide is used. Another point that may well be borne in mind is that patients with high blood pressure can safely take nitrous oxide-oxygen, as under it the pulse is slowed and we have a temporary engorgement of blood in the capillaries, lessening the strain on the heart. The danger attendant upon struggling and excitement is avoided.

And lastly a point that appeals to all concerned, the patient following the operation begins his fight for recovery immediately with full consciousness, with less of shock, and with heart, kidneys, and lungs unimpaired. "Literally without encumbrance."

*Read at a meeting of the Chattahoochee Valley Medical and Surgical Association, held at Warm Springs, Ga., July 10-12, 1917.

Oxygen in Eclampsia.—Rössle sees a mechanism which comprises overfeeding with protein and lack of oxygen. He treats eclampsia in part with subcutaneous infusion of oxygen and intravenous injection of hydrogen peroxide.—*Correspondenz-Blatt für Schweizer Aerzte.*

Action of Poison Gases on the Eye.—Teulières and Valois have seen many examples of injury to the eyes from deleterious gases in the Ophthalmic Center of the XIII Region. The subjective symptoms agree throughout with those produced by the introduction of active irritants in the conjunctival sac—prickling, lacrymation, blepharospasm, and photophobia. These are sufficient to bring about subjectively diminished vision, irrespective of the state of the fundi. Dyschromatopsia, contracted visual field, and scotomata were never noted. Objectively there is a severe conjunctivitis of the dry type with slight chemosis and at times swelling of the lids. The pupil as a rule is sluggish. There are evidences in the worst cases of neuroretinitis. The outline of the papilla is partly effaced. Vision may be reduced even as high as 80 per cent. Nevertheless the outlook in these cases is favorable.—*La Presse Médicale.*

Military Medicine.

THE SOLDIER'S HEART AND CIGARETTE SMOKING.

DURING the past two years there has been much discussion and a great deal of writing concerning that condition known as the irritable heart of soldiers. More than one theory as to its causation has been brought forward. Sir James Barr, dealing with the question in *American Medicine* for September, 1916, attributed the condition mainly to hyperthyroidism, a conclusion which has been accepted by a good many observers. Barr claimed that he had cured several cases of irritable heart by treating the condition as one of hyperthyroidism. Recently, Drs. John Parkinson of London and Hilmar Koefod of Harvard have been making investigations as to the effect of cigarette smoking on healthy men and in cases of "soldiers' heart."

The results of these investigations, published in *The Lancet* of August 18, 1917, are summarized as follows: (1) The immediate effect of cigarette smoking upon the circulatory system and upon the breathlessness of exertion was observed in 30 smokers, of whom 20 were subjects of "soldiers' heart" and 10 were healthy soldiers. Each subject smoked four or five cigarettes during a period of 40 minutes. (2) A demonstrable effect was recorded in 17 of the 20 patients, the 3 unaffected being non-inhalers. Nine of the controls, all inhalers, were influenced in the same fashion, though not to the same degree. (3) The average pulse rate among the patients during smoking was nine beats higher than before smoking; in the healthy controls it was six higher. Initial slowing of the heart was never observed, nor was any irregularity referable to smoking. (4) The rate of respiration in the patients was unaffected; in the controls it was slightly reduced. (5) The average systolic blood pressure was raised 5 to 10 mm. Hg. and the diastolic 5 mm., in both patients and controls. (6) These effects appeared within five minutes; with the first cigarette they almost reached the maximum, and this was maintained throughout the smoking period. (7) A simple exertion test was performed before smoking and repeated on its cessation. In the patients the pulse rate maintained a higher level throughout the test after smoking and half of them were more breathless both subjectively and objectively. In two patients precordial pain was induced by smoking, apart from exertion. But in the controls the pulse rate curve during exertion was much the same after smoking as before, and breathlessness was induced in two only. (8) These observations show that in health the smoking of a single cigarette by an habitual smoker usually raises the pulse rate and blood pressure perceptibly; and these effects are a little more pronounced in cases of "soldiers' heart." Moreover, the smoking of a few cigarettes can render healthy men more breathless on exertion, and manifestly does so in a large proportion of these patients. (9) Excessive cigarette smoking is not the essential cause in most cases of "soldiers' heart," but, in the opinion of the writers, is an important contributory factor to the breathlessness and precordial pain in many of them. The truth seems to be that the large majority of cigarette smokers are inhalers, and it is the inhaling of the smoke that is harmful. A man who inhales tobacco smoke to a large extent is unable to keep himself in hard condition, in the condition, in fact, in which a soldier at the front ought to keep himself. A man who is not in the highest state of physical efficiency is obviously not so good a fighting man as he who is in such state, and if excessive cigarette smoking is a contributing factor to physical inefficiency, it is the duty to curb the desire in this direction. Moreover, it must be borne in mind that some individuals are more susceptible to the effects of tobacco smoke than others. For these reasons it is a pity that so much is said now in the papers about the soldiers' smokes. *The Sun* of this city is contributing largely to the comfort of tobacco addicts in the army by its campaign to supply the tobacco and cigarettes that the Government does not give. One possible untoward effect of its zeal, however, is the spreading abroad of the idea that smoking is soldierly, that it is a part of the game; and doubtless many non-smokers are tempted to take up the habit, induced thereto by a sort of crowd contagion. On the contrary, the fact should be emphasized that the tobacco is for those who have already acquired the habit, this not being the time and somewhere in France not the place for the men to be made to suffer the great discomfort caused by withdrawal of their solace; but that this is not the time nor is anywhere the place for the new men to take up the habit deliberately. It will not add to their efficiency, but will rather expose them to the danger of becoming less efficient if they smoke too much or if for any reason their supply of the dope is temporarily cut off.

Surgical Efficiency in the British Navy.—In the *British Journal of Surgery* for July, 1917, Arthur W. May, Surgeon General of the British Navy, describes the advances made in recent years in the efficiency of that service. He states that the growth of surgical efficiency in the British Navy has been very marked during the past twelve or fifteen years. Up to that time major surgical operations were rarely undertaken and there was a great loss to the service of men invalided for such disabilities, as hernia, varicose veins, etc. Coincident with the more general employment of surgical means elsewhere, the spirit of surgical enterprise arose in British naval hospitals. It did not originate, as might be supposed, from the influx of new blood, or from suggestions by the administration. It arose from the enterprise of a few pioneers, men of several years' seniority, who, developing a latent ability, with courage and determination fought down prejudice and laid the foundation for that confidence in the surgical work of their hospitals that is now shown by all ranks of the service. This growth of efficiency was fostered by the Administration. The hospitals were provided with every surgical necessity. Old operating rooms were reconstructed and new rooms added. X-ray departments were instituted. The new hospital at Chatham, built during this period, was furnished with the latest surgical apparatus. Officers were selected and appointed to all the large hospitals as anesthetists

and radiographers. As many medical officers as arrangements permitted received post-graduate instruction at recognized schools. These courses included special instruction in operative surgery. No difficulty was found in obtaining a succession of senior medical officers capable of taking up the surgical work. There seems to be no doubt that a close association with the strenuous activity that exists in the fighting branch of the navy develops the qualities of handiness and adaptibility, and in such practical subjects as surgery, radiography, and bacteriology the seasoned naval medical officer quickly becomes efficient.

While the practice of surgery was being encouraged in the hospitals by the provision of all requirements, the surgical equipment of the ships was greatly improved. Special stations for the treatment of wounded during action were considered in the design of the vessels and not left to be extemporized as had been the custom. These stations were fitted with a supply of hot and and cold water, special ventilation, lighting, and equipment generally. Formerly the surgeon had to provide himself at his own expense with a regulation set of surgical instruments, a stomach pump, splints, and a few other necessary articles. For some years past all the larger ships have been supplied by the Admiralty with a liberal outfit of instruments, including microscopic and sterilizing, *x*-ray, and bacteriological apparatus, and recently a medical library of reference has been added. These stores are supplied from the naval hospitals, where they are kept ready packed to be issued at a moment's notice.

In addition to being hospitals proper, and centers for distribution of stores, these establishments are training schools for male nurses. In peace time courses of lectures are given by the staff to medical officers attached to or in the vicinity of the port. For over thirty years the Royal Naval Hospital at Haslar has been a training center for newly entered surgeons. Within recent years the newly entered have been required to pass an examination at the end of a period of probation before receiving their commissions. During the war, however, all regular courses of instruction at Haslar and Greenwich have been suspended. At the outbreak of hostilities, fighting ships in commission and those newly commissioned received their war complement of medical officers and medical stores. The hospitals were brought up to their full war accommodation and staff, and the prearranged scheme for overflow to the subsidiary naval infirmaries and temporary hospitals was put into force. This scheme has been considerably expanded, especially in Scotland, to meet the growing necessities of the fleet. Hospital ships have been equipped and staffed and private yachts fitted out by their owners, have been taken over by the Admiralty as hospital ships for the transport of the sick and wounded over short distances. A great deal of surgical work has been undertaken in hospital ships, both while acting as mobile base hospitals to the fleets and while carrying naval and military wounded. A share of this operative work has been borne by temporary surgeons. The employment of hospital ships as mobile base hospitals enables the fleet to use suitable bases without regard to considerations as to the disposal of the sick and wounded, and as these bases or rendezvous may be a considerable distance from the naval establishments ashore, the transport of the acutely sick and wounded is reduced to a minimum. During the military operations in the Gallipoli Peninsula naval hospital ships in the Mediterranean were employed chiefly in receiving the wounded direct from the dressing stations and transporting them to base hospitals in Egypt, Malta, and elsewhere. Although the number of casualties coming under treatment after naval actions afloat have been comparatively few, the naval home hospitals have been very full at times, since accommodation has been given to the British and Belgian military as well as to the sick and wounded from the men of the Naval Division fighting ashore. Afloat, the organization for the immediate treatment of the wounded varies with the class of fighting ship. In all ships the sick berth is situated in too exposed a position to be used during action. Two main stations are selected, one forward and the other aft, in the best protected and most accessible situations. Here the wounded are brought together by collecting stretcher parties during pauses in the fighting. After treatment they are passed on by distributing stretcher parties to disposal stations. Many of the cases receive first aid treatment at the hands of their comrades before they arrive at the receiving stations, for dressings, tourniquets, etc., are provided in all turrets and isolated positions.

The experiences gained in the present war have proved the value of the instruction in first aid given to the ship's company; this is especially noted in unarmored ships, where it is practically impossible for the wounded to be collected or for the surgeon to reach the wounded during action. In the work of attending the injured the surgeons and staff are assisted by officers and men of the non-combatant branches. All details of the organization are rehearsed frequently in a realistic manner.

Before going into action the men are required to change into clean clothing in order to lessen the liability to septic infection, but sepsis from the presence of virulent microorganisms rarely occurs afloat. This freedom has permitted the complete closure of severe shell wounds to be made after excision of damaged tissues, with results that are most encouraging. The large proportion of burns on uncovered parts of the body have called for special measures for the protection of the face and hands. The treatment of burns by recent and improved methods is securing careful attention.

Syndrome of Acroparesthesia a Frigore.—Although much has been written on the results of exposure of the extremities to the cold and damp of the trenches, the subject of extensive and permanent alterations of sensibility from the same causes has received comparatively little attention. Cottet discusses it at length in *La Presse Médicale* for September 8. These occur alike in the frost bitten and intact soldier. Sensation is seldom abolished outright but is diminished in all of its expressions—tactile, thermal, etc.—but analgesia is especially marked. The soldier is

quite unaware of a pin prick or a pinch. Hence by means of a pin it is possible to delimitize the affected area. The contrast is marked between the indifference on one hand and the defence reactions on the other. The examination is, of course, made in perfect silence in order to avoid suggestion.

In the lower extremities the hypoesthesia begins at the ankle and extends upwards along the leg and even to the thigh. It is only exceptionally that the entire foot is involved. Several types of diminished sensation are described. The sole of the foot is invariably involved, but in the anterior dorsum sensibility may not only be preserved but even increased. The plantar reflex may be abolished when hypoesthesia appears to stop sharply at the knee, it may be found that in the skin of the thigh, sensibility is sensibly diminished.

In the upper extremity the entire forearm is involved and in some cases there is more or less alteration of sensibility in the skin of the upper arm. The back of the hand is hypoesthetic, while in the palm sensation is normal or even slightly hyperesthetic. There is often diminished sensibility in the nose and ears. In a schematic arrangement in three zones, denoting marked hypoesthesia, slight hypoesthesia and normal sensation, the legs and upper dorsa of feet, forearms and backs of hands, nose and ears (and soles of feet) are colored black to denote the more pronounced diminution of sensibility, while the thighs and upper arms are represented as moderately or slightly involved. The head and face (with exceptions noted), neck, trunk, buttocks, palms of hands, and most of the dorsa of the feet are represented as quite intact. This distribution resembles nothing else in pathology unless hysteria, and hence may be assumed to be a distinct entity. There is, however, something besides hypoesthesia here, at least, in certain cases: further disturbance of sensation, such as vague pain, dead or heavy feeling of legs, formieation, cryesthesia, etc. Even in bed the legs feel cold, are goose-skinned. On inspection some vasomotor disorder is evident, as shown by a violaceous, marbled coloration. In fact, acroasphyxia in both the livid and pallid forms is sometimes beheld. Finally a trophic element is seen in certain deformities of the nails.

As for the nature of this affection it stands in some relationship with the well known group of affections of the extremities of which Raynaud's disease is the most prominent member. On the other hand, it is also related to other affections of the parts due to exposure, as chilblains and frost bites. But in all of these allied affections the digits bear the brunt of the exposure and present the most characteristic lesions. Acroparesthesia, in which the digits are not seriously or characteristically involved, must have a special mechanism, but none such is yet in evidence. The resemblance to hysterical analgesia is considerable and for all we know there may be a psychogenic factor underlying these cases. But the rapid response to warm applications of all kinds suggests that mere refrigeration is the essential factor.

Certain Military Aspects of Hookworm.—Charles Wardell Stiles in Public Health Report No. 418 relates that a newly formed militia unit was quartered temporarily at a Government reservation where he was conducting some experiments. Within less than two days after reaching their quarters one of the recruits was suspected of trying to shirk his duty and the commanding officer planned to place him in confinement for discipline. The man claimed that he was not feeling well and he (Dr. Stiles) was requested to pass upon the case medically. The diagnosis of light hookworm infection was made upon the symptoms and soon confirmed by microscopical examination. On the third day after reaching quarters a second recruit was brought for examination. Again the diagnosis of hookworm infection was made and confirmed. Later it was found that in a total of 75 militia recruits 47, or 63 per cent., showed hookworm infection. Treatment of these infected men was instituted with the result that the gain in weight and efficiency were so marked as to produce comment even from the nonmedical men. Dr. Stiles points out that this experience has its lessons in the present war. These recruits represent an unselected instance of what may be expected in certain portions of the country among average enlistments. Two volunteers were rejected because of remediable conditions clearly due to hookworm infection, and these men represent instances of a very large number of cases that will probably soon be noticed both in the Gulf Atlantic and the southern Pacific regions. Several recruits were rejected because of underweight. If such recruits are the victims of hookworm they might justifiably be accepted provisionally if the regulations permit. A failure to treat the hookworm cases and to eliminate at least the severe infections of *Strongyloides* will undoubtedly result in unjust and preventable punishment for offenses due to remediable conditions, considerable physical and mental inefficiency, an unnecessarily high daily "sick call," and premature and preventable pensions. If even light cases of infection with hookworm are sent to the trenches in Europe the danger is present of causing a widespread epidemic not only among military forces but also among the civil population of France and Belgium. All these dangers may be prevented to a very great extent if all the recruits, or at least those from certain states, are systematically examined for intestinal parasites and either treated in American camps or discharged, as necessity indicates. The examination can best be a three-slide (10-cover glass) test, preferably by the centrifuge method. If an examination for hookworm only is made the work will be considerably lessened. This examination could be made more economically, more efficiently and more rapidly at a central laboratory than in separate concentration camps. Dr. Stiles suggests that it would be wise to begin promptly with all units at present organized and to combine the examination with a newspaper campaign to induce prospective recruits to take the initiative to have themselves examined and treated.

Prophylaxis and Treatment of Frostbites with Tar.—Aside from trench foot congelations occur as a result of fighting in the snow, especially in

high altitudes. This occurs in the most marked degree on the Italian front, and naturally some familiar, permanent, inexpensive substance which could serve both for prophylaxis and treatment would be a great desideratum. As a rule, the management of congelations has involved the use of asepsis and stimulation of the circulation, and many individual applications and procedures have been tested, beginning with protective coverings. Massage and frictions with vaseline, camphor and alcohol, progressive warm baths, and various antiseptic and aseptic dressings, have been employed to fill indications. But while members are saved, the men are incapacitated for a long time. In the deeper degrees of congelation sloughs must come away. Hence prophylactic measures must be tried out. Rabbi, a captain surgeon in the Italian army, thinks he has discovered a very superior remedy in Norwegian tar, which is hostile to fungi, saprophytes, and disease parasites, which protects against humidity and is itself practically stable. Tar contains many substances of antiseptic powers (phenol, creosol, naphthalin, toluol, benzol, etc.). As used by the author, no local or general phenomena have been set up, and renal irritation from elimination has never been seen. Cases cited by the author include both trench foot and mountain congelation. In an example of the latter we note that the soldier was admitted for congelation of the first and second degree, involving both feet. These were edematous, livid, and the seat of bullæ. Sensibility was lowered, movements difficult and painful. The prognosis was that the process would reach the third degree. The feet were at once tarred. Four days later lividity had disappeared and swelling was much reduced, while pain was less and the feet felt warm. In two more days patient was able to walk without pain. Epidermis came away, leaving normal skin beneath. The patient was pronounced cured 14 days after admission. The number of cases treated was small, and dry gangrene alone was encountered. Whether the remedy would be equally valuable on moist gangrene remains to be seen.—*Giormale di Medicina Militaire*, February 28.

System of Red Cross Warehouses in France.—The Red Cross authorizes the statement that it has established a system of thirteen large warehouses throughout France for the purpose of distributing supplies to the numerous war hospitals behind the French firing line. Six of these warehouses have been located in Paris, which serves as the center of the system. The supplies are distributed to the hospitals by motor trucks and wagons. Approximately fifteen tons of materials are being distributed monthly from these warehouses, most of the supplies coming from the United States. Plans are now under way to increase the warehouse facilities at French seaports, as at present these are very limited. The stock of supplies carried includes not only those required for hospitals, but also food stuffs, clothing, building materials, farming implements, etc., needed in the work of reestablishing the French refugees. The Paris warehouses alone can care for 60,000 tons of supplies at a time.

Commissions in the Medical Reserve Corps.—The announcement is made from Washington that the issue of commissions in all Staff Corps of the Army, including the Medical Department, have been suspended temporarily pending the preparation of a report by the Adjutant General showing the number of officers in each corps and comparing the number now commissioned with the prospective needs of the different services. At the same time officers of the Medical Reserve Corps, inactive list, are informed that assignment to active duty may be delayed and they are therefore advised not to discontinue their civil practice pending receipt of orders. They will be given a fortnight's notice when their services are required.

American Fund for French Wounded.—This organization has made an agreement with the American Red Cross whereby the two organizations can work in harmony without the American Fund for French Wounded losing its identity. The American Fund is to maintain its present status, to collect funds in its own name, and to continue the manufacture of supplies. The Red Cross will transport to France standardized supplies furnished by the American Fund for French Wounded. A satisfactory understanding has also been arrived at whereby the two organizations will work in cooperation in the distribution of supplies in France.

Base Hospital Fire.—The base hospital at Camp Wheeler, near Macon, Ga., caught fire on the night of October 23. It became necessary to call out the Macon Fire Department in order to get the fire under control.

Moss as a Surgical Dressing.—A correspondent of the *New York Times* calls attention to the possibility of using sphagnum or peat moss as a surgical dressing. Owing to the very limited supply of cotton that the blockade permits to get into the Central Empires, the Germans have been using this substitute on fresh wounds and claim that it absorbs from seven to ten times its own weight in liquid while cotton absorbs only six times its weight. The moss also dries more quickly than cotton. Although the Allies have not yet had to contend with a shortage of cotton, attention is called to the fact that this moss grows in large quantities in the State of Washington, and Prof. John W. Hotson of the botanical department of the University of Washington has been supervising the collection, cleaning, and drying of this moss for Red Cross use. The dried moss weighs almost nothing and can be easily shipped.

Dispensary Unit for French Relief.—The Chicago Committee of the American Fund for French Wounded is forming a dispensary unit for relief work among the civil population of France. The unit will sail soon and expects to join the first babies' relief group sent from Milwaukee two weeks ago. Dr. Clara M. Davis has charge of the unit.

Louis J. Horowitz, President of the Thompson-Starrett Company of New York, has been appointed director of Foreign Relief of the American Red Cross. He will serve without compensation.

Defects in Spartanburg Base Hospital Remedied.—Complaints widely published some days ago as to the unsatisfactory construction of the base hospital at Spartanburg were brought to the attention of the War Department and as a result orders have been issued to install ceilings, to reinforce the building throughout, and to purchase whatever was deemed necessary for the comfort of the soldiers.

STATE HOSPITALS AND THE WAR.

MANY, if not most of us, are accustomed to think of the vast numbers of insane persons populating our State hospitals as a dead loss to the nation. Even the most ardent advocate of the conservation of national resources is apt to turn away from this problem to others which offer more promise. And yet, in this time of war, we have no right to assume hastily that there is no economic gain to be had here; if these half-million or so dependents can help the nation in any way—if they can even lessen to some extent the burden of caring for them—let us see how.

A few pregnant suggestions are given by Dr. White in an article in *Mental Hygiene* for July, 1917. He calls attention to the great strides which occupational therapy has made in recent years and suggests that the proficiency to which patients and attendants have attained be turned to account in winning the war. Every inch of available land should be cultivated. He says, "There should be no hesitation in plowing up lawns, no matter how beautiful, provided the land is such that a worthwhile crop may be expected." Even women patients can tend small plots of ground. Aside from the economic advantage there is a stimulating effect on the patients themselves. White calls attention to the various industries which have sprung up in State hospitals—brushmaking, broommaking, matmaking, chaircaning, shoemaking, tailoring, cement work, and so on. Because of the fact that the chief desideratum has been the good of the patient, the output from these industries has been kept down to a minimum. But now each hospital might well concentrate on one line of work and over-produce as much as possible, the excess being used to help the country. For example, all the hospitals of one State could make shoes, and turn their products into the State for equipping the militia, or to the Federal Government for equipping the army.

In fact, nearly any form of State hospital activity can be turned to use. The women patients can knit and sew for the soldiers and sailors. Hospitals in rural districts which have a large number of patients accustomed to farm labor can send out squads of patients to help neighboring farmers gather in crops which otherwise, owing to the shortage of help, might be spoiled. How much better is such occupation for diseased minds than purposeless labor like that described in Charles Reade's "It's Never Too Late to Mend," whose convict, it will be remembered, had to turn a crank all day long, the aim being simply the recording of so many revolutions; or the old custom of having prisoners dip sea-water on one side of an island, carry it across and pour it into the ocean on the other! Even the custom in some hospitals of encouraging the women patients to do fancy work will not bear scrutiny. For it is easy for such "work" to become mere automatism—the flying fingers turn out yard after yard of intricate and useless embroidery while the brain, the personality itself, is busy with a world of fantasy. Exactly what we want to avoid in the average mental case.

Last, but not least, the psychiatric units which the National Committee for Mental Hygiene is undertaking to equip and furnish must look to the staffs of such State hospitals for their own personnels. Where else can be found doctors and nurses with training in the care of mental cases? Then, too, with an army of a million or more, St. Elizabeth's Hospital at Washington will hardly accommodate the mental cases which will undoubtedly eventuate and various State hospitals will probably be called upon to take care of many such patients.

In all these ways, then, the inmates of State insane asylums are assets rather than liabilities. Perhaps the time will come when a central committee will take under its care all State hospitals and collate their resources so that each hospital or group of hospitals can specialize in one particular product to the benefit of the whole. And who shall say that the thought that one is doing his bit for his country, the thrill that comes from patriotic effort, will not permeate the most deteriorated mind and raise it a step or two toward the light?

THE MICROPHONE AS AN AID IN REMOVING FRAGMENTS OF NEEDLES FROM THE TISSUES.

ALL surgeons who have had the unpleasant experience (and who has not?) of failing to locate a fragment of needle in the hand after careful dissection and a long and tedious search, will appreciate the value of the method to which attention is called by Kenneth Bulkley in the *Annals of Surgery* for July, 1917. In a previous article Bulkley described the theory of the apparatus and also its method of application. In his latest communication he quotes statistics of 72 cases of needles in the hand or foot met with in the four surgical services at Bellevue Hospital, and 33 of his own cases operated upon with the aid of the microphone.

Of the Bellevue cases 54 had fragments of needles in the hand and 18 in the foot. The distribution in the hand was: Thumb or finger, 20 per cent.; thenar eminence, 44 per cent.; hypothenar eminence, 10 per cent.; front of wrist, 10 per cent.; remainder

of palm, 10 per cent.; and dorsum of hand, 4 per cent. These were not dispensary cases, but all the patients had been admitted to the wards of the hospital. In 8 cases, for one reason or another, no attempt was made to remove the needle. The difficulty of finding these needle fragments by ordinary dissection methods is well shown by the results of Bulkley's study of the remaining cases of this group. The needle was found on the first attempt in only 47 per cent. of the cases, 17 with local and 30 with general anesthesia. The results in the remaining 53 per cent. were as follows: In 13 per cent. one attempt only was made and the needle was not found; in 10 per cent. the needle was searched for twice and not found; in 24 per cent. the second attempt was successful; in 5 per cent. the needle was found on the third attempt; and in one case the needle was not found until the fifth attempt had been made.

Making use of the microphone, Bulkley's results in 33 cases of embedded metallic foreign body furnish a startling contrast to those quoted above. In 25 of these cases the foreign body consisted of part of a needle, the distribution being 20 in the hand, 1 in the foot, 2 in the capsule of the knee joint, and 2 in the back. There were but two cases in which he had much trouble, in spite of the fact that in over one-third of the cases one or more previous attempts at removal had been made. In one case the fragment was free in one of the tendon sheaths and had moved several inches down the sheath after the *x*-ray plate had been taken. Another plate showed its new location and the fragment was readily removed. In the one case in which Bulkley failed to get the needle fragment there was a powerful dynamo in the next room, invalidating the microphone. One must, therefore, agree with the author when he says that he feels very strongly that a method capable of reducing primary operative failure in the removal of needles from 53 per cent. to 3 per cent. is worthy of more extended trial.

IS ARTHRITIS DEFORMANS INFECTIOUS?

It is hardly necessary, before an audience of physicians, even to allude to the obscurity of chronic joint diseases. The universal familiarity with the clinical condition in these affections contrasts sharply with the lack of understanding of the morbid findings post mortem, or rather with the variety of interpretations of such findings. Even where we know that the joint disease must be due to a definite organism, as, for example, when we have tuberculous or syphilitic arthritis, we have not as yet been able to find a specific reaction in the joint tissues in correspondence with specific morbid factors. The etiology of arthritis deformans, for example, brings out marked differences of opinion. Presenting, as it does, many of the ear-marks of an infectious disease we still lack the indispensable proof of this.

Some time ago Dr. P. W. Nathan (*Journal of Medical Research*, May, 1917) conducted a series of experiments and studies of cases with the theory that arthritis deformans is infectious. He concluded from what is known of the histology and pathology of the joints that all the morbid changes to be found in joint disease can be ascribed to variations of an inflammatory process; these changes are not specific, nor do they correspond to definite clinical entities. The hypertrophic and so-called metaplastic changes are due to the reaction of the quasi-embryonic cells in the joint structure.

Having made these deductions, Dr. Nathan proceeded to verify them by experiments on dogs, after the example of J. Koch, who inoculated dogs with hemolytic streptococci to determine the localization of microorganisms in the bone marrow. Dr. Nathan used twelve dogs, killing ten of them at intervals from the third to the ninetieth day; two of them died marantic, one at two and one at twenty-eight days.

It is impossible, of course, to repeat here his extensive findings, which should be read by those who are interested in the original. Suffice it to say that he found that, in spite of the apparent variations, the principal gross and microscopical findings in both acute and chronic joint disease, whether of known or unknown origin, are fundamentally simply phenomena of an inflammatory reaction. All forms of arthritis, he says, are due to inflammations of infectious origin. The pathological lesions correspond exactly with those of known infections and the variations in phenomena can all be ascribed to differences in the location and virulence of central or peripheral nerve involvement.

We must then look for the original focus of infection, perhaps an ulcerated tooth, perhaps a tonsillitis. Dr. Nathan has found that, in treating the local condition, where the joint is not destroyed or ankylosed, thymus extract nearly always leads to more or less complete recovery. Omit, he says, the routine and the mechanical treatment which are both so harmful.

A PSYCHOLOGIST ON THE "APACHES."

To regard the so-called "Apaches" as peculiar to Paris is to ignore the fact that all great modern cities have a race of antisocials of the lowest substratum whose sole occupation is mischief—for whatever purpose. These people are savages in the midst of civilization. In *El Siglo Medico* for September 22, Sanchez-Herrero attempts to show that this species of mankind is actuated by a complete absence of sense of correct values. They "have to be shown," for they believe only what they can see and feel, and thus undervalue all other methods of assurance. They have no sense of brotherhood, even though banded together for self-interest. Neither affection nor indifference, but only hatred represents their sentiments toward mankind, as expressed in the twofold way of robbery and assassination. The Apache has neither the ethical nor the esthetic feeling which distinguishes civilized from savage man. He is extremely vain, and really regards himself as superior to his prey. This egotism makes it impossible for him to recognize authority, and he re-

bels at the idea of work of any kind. It is constant toil which saves the ordinary man from his own disposition to evil. The Apache, without this discipline, must live from those who do work. His only idea of acquisitions is necessarily material, for he can have no conception of the value of character or other immaterial riches. His sexual standards are of the lowest, for he maltreats his women, practises unnatural vice, and attacks children. Of family life or faithfulness to one woman he has, of course, no conception. He is likewise devoid of all religious sentiments, but in their place are degrading superstitions—beliefs in amulets, etc. The Apache is a complete atheist, for he has no thought of a Supreme Being. This attitude toward religion makes it easy for him to butcher his victims without warning. He attacks in the dark and from behind. We have only to consider the sense of values of the educated, conscientious subject to obtain an idea of the Apache mind. The first-named believes that he was put in the world for a purpose—for many purposes—to think, feel, seek out, understand, progress. But these are all abstractions which mean nothing to an untaught man who can believe only in material things. The Apache simply has no internal existence of any kind. It is hardly necessary to add that he is not merely ignorant and raised in a poor environment, for he is also a complete moral degenerate.

Marked Tolerance of a Subject of Addison's Disease to Adrenalin.

It is commonly admitted that suprarenal extracts can do little or nothing for the relief of victims of Addison's disease. The latter is a chronic process in which the suprarenal bodies are doomed to destruction and the action of adrenalin is only transitory. That it is not entirely indifferent, however, is well shown in an article by Nolf and Fredericq in the *Archives Médicales Belges* for August. A patient with Addison's disease who suffered notably from hypoadrenalinemia was seen to enjoy a sort of immunity to the toxic action of the drug. The diagnosis was confirmed by autopsy for the tuberculous subject showed caseation of both adrenals. The drug had been given for the low blood pressure. On a single occasion 10.5 mg. of the pure substance was injected during a period of 4½ hours. If, as Josue claims, the maximum permissible dose is 2 mg. in 24 hours by the subcutaneous route the authors exceeded this many fold and moreover 8.5 of the 10.5 mg. were given intravenously. The fear is of causing acute edema of the lungs. However interesting this episode may be, it loses, perhaps, some of its force through the fact that large quantities of adrenalin taken with suicidal intent have been well borne. On the other hand, the innocuousness of such a large amount injected into a vein shows that remarkable tolerance was undoubtedly present in this particular individual.

Bacteriology of Hodgkin's Disease.

The nosological status of Hodgkin's disease and its congeners has been far from clear, and all attempts to group it, either with chronic infections, neoplasms, or hematoses, have come to grief. Bacteria described as peculiar to the disease have not been lacking, and Dias of the Oswaldo Cruz Institute at Rio has recently described a new one (*Brazil Medico*, August 25). The high scientific reputation of the staff of this institute, with the possibility that the affection as seen in South America may differ in some respects from that in the Northern Hemisphere, make this claim of no little interest. The newly discovered organisms appear to comprise both bacilli and fungi, or rather certain of the elements resemble bacilli; the fungi resemble yeast cells, and are smaller than blastomycetes. These are also oblong formations, and rarely true hyphæ have been seen in smears. Finally, there are indeterminate formations. These bodies can all be seen in smears from cut glands. Cultures are obtained by direct and indirect methods. Despite the variety of pleomorphism the author evidently regards the basic organism as a fungus, which to some extent—in sporulation, for example—behaves like the ray fungus. The author has been at work on this subject for years, and feels so well satisfied that the cause of Hodgkin's disease has been discovered that he terms the latter "adenomycosis."

News of the Week.

Decrease in Birth and Marriage Rates in Germany.—A special correspondent of the New York *Sun* quotes statistics from an article in a prominent German Socialistic organ which show that since 1915 the number of deaths in Germany has exceeded that of births. In 1914 this decrease was 18,500; in 1915 it reached 423,000, or an increase of deaths over births of 23 per cent.; in 1916 it reached 40 per cent. The low birth rate, however, has been partially counterbalanced by a decrease in the infant mortality rate of about 40 per cent. It is pointed out that this decrease in the birth rate is based on peace-time figures and that it should have fallen off to a much greater extent than the birth rate. During the first month of the war there was a marked increase in the number of marriages, but this was followed by a sharp diminution which has continued to the present time. In Saxony there were 26,300 marriages in 1915 as against 40,300 in 1913; in Hamburg the corresponding decrease amounted to 2,300; in Berlin to 5,000, and in Bremen to 1,000. The writer points out that this decrease in the birth and marriage rates will work greater injury to the future of the German Empire than its losses on the numerous battlefields.

Prenatal Instruction to Mothers.—The *Weekly Bulletin* of the Department of Health of New York City, for October 13, quotes statistics to show that if we are to make further progress in reducing the infant mortality rate it must come through concerted effort directed against deaths from congenital diseases, and during the first month of life. Feeling that this is the work of the future, the Health Department has organized a special group of nurses to instruct mothers during the period of pregnancy in all matters pertaining to home and personal hygiene, diet, and all matters which make for healthier mothers and more vigorous children, and for a reduction in the number of stillbirths. These nurses are at

present assigned to a limited number of Baby Health Stations. In addition to this the nurses in charge of the fifty-nine Baby Health Stations throughout the Greater City are prepared to give similar instruction to prospective mothers. General practitioners are urged to notify the Baby Health Station nurse of those cases, which, in their opinion, would profit by prenatal instruction. The nurses will thereupon visit such mothers and advise and instruct them without encroaching upon the authority of the family physician. At the request of the attending physician or with his permission, a urinary test for albumin will be made and positive findings reported.

Public Health Committee of New York Academy of Medicine.—The report of the Public Health Committee of the New York Academy of Medicine, from May to September, inclusive, shows that it has been active in many fields. In addition to giving its advice and cooperation in the solution of local problems, it has adopted and forwarded resolutions to the several members of Congress who were particularly interested, urging that Congress take such means as seemed fitting and proper to enable this country to supply salvarsan or its equivalent to the medical profession. It has cooperated with the New York County Chapter of the Red Cross in securing free medical services for civilian relief work among the families of soldiers and sailors who find themselves without means of securing adequate medical attention. It has made a protest against the bill depriving the health departments of New York State of the power to exercise control over overcrowding in public conveyances. The committee has also protested against any change in the vaccination laws and disapproving the bill to amend the tenement house law allowing three-story private houses to be converted into three family tenements. It has cooperated actively in the campaign for securing a change in the ruling of the War Department concerning the drafting of medical students and internes. Dr. John S. Billings, Dr. Walter I. Niles, and Dr. Herbert B. Wilcox have been added to the membership of the Public Health Committee.

Law Fails to Protect Women in New Employments.—Owing to the difficulty of securing male elevator operators, the agents of many apartment houses in New York City have employed women to act as elevator operators. In response to a complaint to the Department of Health that many of these women were employed under conditions fraught with danger to health and morals an investigation has been made which shows that in some instances the complaints are well founded. The fact has been brought out that under the present laws regulating the conditions of employment for women the State Labor Law only provides for the regulation of conditions of employment of women in factories, shops, and stores. The Department of Health will keep these apartment houses in which the conditions of employment are not what they should be under observation and will endeavor to find some way to safeguard the health of these women.

New Venereal Clinic.—The Health Department of New York City announces that in order to provide dispensary service in venereal diseases to the residents of Jamaica and Flushing, a venereal clinic has been established in the Queensboro Hospital of the Department of Health. At present the clinic is conducted three days a week, Mondays and Fridays from, 3 to 4.30 P.M., and Wednesday evenings from 6 to 9 P.M.

Microscopical Exhibit.—The Annual Exhibition of the New York Microscopical Society will be held at the American Museum of Natural History on the evening of Saturday, November 3, to which the public has been invited. In addition the slides representing the use of the microscope in the arts, sciences, and industries, there will be a demonstration by the Department of Health of the practical use of the microscope in safeguarding public health.

Combined Meeting of Pediatric Societies.—The annual meeting of the New England Pediatric Society, the Philadelphia Pediatric Society, and the Section on Pediatrics of the New York Academy of Medicine will be held in New York City on November 8, and will include a clinical day, a dinner at the Harvard Club, and after-dinner addresses on the "Pediatricians' Part in the War," by Dr. Alonzo E. Taylor, Dr. Hermann Biggs, Dr. Richard M. Pearce, and Dr. Samuel McC. Hammil.

The Simon Baruch Public Baths.—A tablet in honor of Dr. Simon Baruch, commemorating his connection with the campaign for public baths, was unveiled at the Rivington Street Baths, New York City, on October 29, and these baths were renamed "The Simon Baruch Public Baths." Borough President Marcus M. Marks made an address of acceptance on behalf of the city. The tablet was donated by Mrs. Belle Baruch through the Association for the Promotion of Hygiene and Public Baths.

The Return or Exchange of Laboratory Products.—The New York Department of Health has recently adopted rules governing the exchange or return of laboratory products. Provided the seals of the original containers have not been broken the Department of Health will, at its discretion, exchange laboratory products at its stations where they have been purchased, provided the time of exchange is not later than two weeks after the date of expiration as noted on the label. The Department of Health will accept the return of products of a value of over $1 and give full credit therefor, if returned within ten days of purchase. It will accept the return of products and allow a refund provided the products are returned not later than five days after the purchase. Rules have also been adopted governing the return of products which have been purchased by health boards outside of New York City, by institutions, municipalities, health officers, etc.

High Cost of Drinking Empties Hospital.—The City Hospital of St. Louis is said to be without a patient in the alcoholic ward and no patient was sent in for treatment during a period of over forty-eight hours. The daily average number of patients in the ward during the last year has been about fifteen, with a high record of forty-five. This shortage of patients is attributed solely to the high cost of liquor.

The Robert Dawson Evans Memorial for Clinical Research and Preventive Medicine of the Massachusetts Homeopathic Hospital will receive about $1,000,000, as residuary legatee of the estate of Maria Antoinette Evans.

The Seventh District Medical Society of the State of Georgia, at its annual meeting in Cedartown, Ga., elected the following officers: *President*, Dr. George B. Smith of Rome; *Vice-President*, Dr. M. S. Richardson of Cedartown; *Secretary-Treasurer*, Dr. M. M. McCord of Rome.

National Dental Association.—This organization held its annual meeting at the Hotel Astor, New York City, during the week of October 22, under the presidency of Lafayette Barber of Toledo, Ohio. The dentists now congratulate themselves on having established their profession on a plane with that of medicine and surgery. The National Dental Society is organized along lines somewhat similar to those of the American Medical Association. Among the speakers at the General Sessions were Dr. E. C. Rosenow of Rochester, Minn.; Dr. Alexis Carrel, and Dr. Victor C. Vaughan of Ann Arbor, Mich. The relation of dentistry to the war formed a conspicuous part of the program. The association voted to subscribe $20,000 for Liberty Bonds.

American Association of Electrotherapeutics and Radiology.—At the annual meeting of this association, formerly called the American Electro-Therapeutic Association, held in Atlantic City, September 11-13, the following officers were elected: *President*, Dr. Frank B. Granger, Boston; *Vice-Presidents*, Drs. V. C. Kinney, Wellsville, N. Y.; William L. Clark, Philadelphia; William Martin, Atlantic City; Alfred T. Livingston, Jamestown, N. Y.; M. G. Campbell, Atlanta; *Treasurer*, Emil Heuel, New York; *Secretary and Registrar*, Byron S. Price, 65 Central Park, West, New York City.

New York and New England Association Railway Surgeons.—This association will hold its twenty-seventh annual session at the Hotel McAlpin, New York City, on November 8, 1917, under the presidency of Dr. H. G. Stetson, Greenfield, Mass. An interesting program is being arranged, information regarding which can be obtained from the corresponding secretary, Dr. Geo. Chaffee, Little Meadows, Pa.

Obituary Notes.—Dr. WILLIAM F. GUTHERSON, a graduate of the College of Physicians and Surgeons, New York, in 1904, and a member of the medical staff of St. Joseph's Hospital, Paterson, N. J., died of pneumonia, on Oct. 24, aged 39 years.

Dr. CARL O. BERNHARDI, a graduate of Rush Medical College, Chicago, in 1901, and a practising physician of Rock Island, Ill., died of pneumonia in the Presbyterian Hospital, Chicago, on Oct. 8, aged 37 years.

Dr. THOMAS J. MCCORMICK, a graduate of Harvard Medical School, in 1900, died at his home in Roxbury, Mass., Oct. 12.

Dr. GEORGE WILLIAM BRUCE died at his home in Moundsville, W. Va., on Oct. 6, at the age of 90 years. He was a graduate of the University of Pennsylvania, in 1848, and for some years Mayor of Moundsville.

Dr. EDWARD MANNING BROWN, a graduate of the College of Physicians and Surgeons, New York, in 1898. a practitioner of Springfield, Mass., died in the Springfield Hospital, on Oct. 22, at the age of 45 years.

Dr. JAMES HOMER DARLING, one of the oldest practising physicians in Connecticut, died at his home in Thompsonville, Conn., on Oct. 8, aged 80 years. He was a graduate of the Burlington (Vt.) Medical College, in 1859, and a surgeon in the Navy during the Civil War.

Dr. GEORGE L. TODD, a graduate of the University of Virginia Medical Department, in 1910, died suddenly in Jackson, Miss., on Oct. 10, at the age of 33 years.

Dr. THOMAS E. ELLISTON, a graduate of the Vanderbilt University Medical Department, in 1880, died after a long illness at his home in Nashville, Tenn., on Oct. 17.

Dr. J. R. EDWARDS, of Denton, Tex., died after a brief illness, on Oct. 10, aged 77 years. He was a graduate of the University of Nashville Medical Department and a surgeon in the Confederate Army during the Civil War.

Dr. PITT H. JONES, a graduate of the College of Physicians and Surgeons, New York, in 1883, a practising physician of Springfield, Me., died suddenly on Oct. 17, aged 55 years.

Dr. LINNAEUS V. GIBBS, a graduate of the Burlington (Vt.) Medical College, in 1880, died at his home in Huntington, Mass., on Oct. 16.

Dr. WILLIAM W. WRIGHT died, after a brief illness, at his home in Huntington, Tenn., on Oct. 6, aged 78 years. He was a graduate of the Washington University Medical Department, St. Louis, in 1869, a surgeon in the Confederate Army during the Civil War, and later superintendent and physician of the State Prison and trustee of the Middle Tennessee Insane Asylum and of the West Tennessee Hospital for the Insane.

Dr. WILLIAM A. MCCALLIE of Knoxville, Tenn., a graduate of Vanderbilt University Medical Department, Nashville, Tenn., in 1875, died on Oct. 18, aged 65 years.

Correspondence.

ALCOHOLIC REMEDIES IN ACUTE SEPTIC DISEASES.

TO THE EDITOR OF THE MEDICAL RECORD:

SIR:—Dr. Abraham Jacobi will have many supporters among the older clinicians in his recent vigorous defence of alcoholic remedies—whisky and brandy—in acute septic diseases. I well remember the extreme use of these remedies in desperate cases of diphtheria by my brother, Dr. J. Lewis Smith, and the happy results which generally followed.

I had an interesting experience when a member of the resident staff of Bellevue Hospital during the great epidemic of typhus fever in 1850-52. Irish immigration was at its flood-tide after a season of failure of the crops and the consequent sufferings from want of food of the laboring classes. Every vessel arriving from Irish ports brought a large number of cases of the fever and as a result not only were the hospitals of the city filled to their utmost capacity with cases of fever, but an immense number were treated in tents at Quarantine. The mortality was enormous in all of the hospitals, largely owing to the enfeebled condition of the immigrants. Eight of our resident staff had the fever, and two of them died. The fever was of

a low typhoid type. After a few days of mild delirium the patient passed into a comatose state which terminated in death at variable periods of one or two days. The treatment pursued was in general sustaining by foods and remedies, but the mortality was so great that death seemed inevitable, especially when the patient became comatose.

Professor Alonzo Clark, a member of the visiting staff of Bellevue Hospital, was giving a course of lectures at the Pittsfield Medical College during the first months of the appearance of the fever. On assuming service he entirely changed the method of treatment. During the first period of the fever he simply corrected any discoverable defects in the patient's physical condition, which generally required little active medication. It was not until the coma made its appearance, indicating profound septic conditions, that he began active treatment, and that treatment was the unstinted administration of whisky or brandy. The directions were to be governed by the symptoms—pulse and respiration—not by the quantity of liquid given. From the adoption of this treatment to the close of the epidemic typhus fever took rank with the most curable diseases of the hospital. Indeed, Prof. Clark once remarked that he was always gratified when a patient passed into the stage of coma, for he was then sure that he had a remedy that would secure recovery.

An interesting incident occurred which put his treatment to a decisive test. On one of his visits he was accompanied by a professor in one of the Medical Colleges of St. Louis, who had heard of Clark's success in the treatment of typhus fever and he came to New York to satisfy himself of the method and its result. He was in charge of a large hospital which received cases of typhus and he was disturbed by the excessive mortality. After a visit to the wards and an examination of cases of coma that he regarded as moribund, Prof. Clark requested him to select such cases as he believed would die before the next morning and visit with him the next day to learn the results of treatment. He selected thirteen patients who he said would die with any kind of treatment that he ever employed.

These patients were removed to a vacant ward and nurses selected to attend them. They were all insensible, but could be partially awakened; pulse small and rapid; respiration spasmodic; eyes slightly closed; tongue dry and with the lips covered with sordes. Prof. Clark directed me to superintend the nurses and give each patient teaspoonfuls of brandy at short intervals and not to be governed by the quantity administered, but entirely by the pulse and respiration. I sat at the bedside of one patient, who seemed to be dying, and gave her teaspoonfuls of brandy every few minutes during the night.

In the morning all of the patients had recovered consciousness with greatly improved pulse and respiration and subsequently made rapid recoveries. The St. Louis professor visited the hospital and examined each patient, expressing the greatest surprise at the remarkable improvement they had made. Still doubtful as to the reality of the test he privately inquired if these were really the patients he had selected, intimating that other more hopeful cases might have been substituted by the attendants.

An amusing incident occurred many years ago at the annual meeting of the American Temperance Union in the Broadway Tabernacle. William E. Dodge, Senior, was the presiding officer and large numbers of the prominent advocates of "teetotalism" were present. The speeches excited great enthusiasm and the climax was reached when the President introduced Dr. Alfred C. Post as a teetotaler and the exponent of the opinion of the medical profesion that alcohol has no value as a remedy in disease. Dr. Post stepped to the front of the platform and in his usual curt speech said, "Yes, sir, I am a teetotaler. I never use alcoholic beverages and never shall while I have my senses, but sir, I could not practise surgery successfully if I were deprived of the use of whisky and brandy."

OUR LETTER FROM PARIS.

(From Our Regular Correspondent.)

HEART WOUNDS—THE BREAD PROBLEM—AMERICAN FIELD AMBULANCE SERVICE—AMERICAN HOSPITAL AT PASSY.

PARIS, September 26, 1917.

INSPECTOR GENERAL DELORME has made an exhaustive analysis, in a report to the Academy of Medicine, of fourteen operations upon the heart for the extraction of war missiles, found either in the body of the muscle or in one of the cavities. In his report of the fourteen cases dating from February, 1915, he described the radiographic aspect, showing the movement of shell fragments, the indications for operative intervention, the choice of route, the accessories necessary and the splendid result of 11 successes out of the 14 operated upon. The general question and consideration of operative procedures for wounds of the heart has arisen during the present war and thanks to French initiative has met with that degree of success which establishes the operation as a fixed addition to surgery, at the same meeting the Academy adopted by unanimous vote the project of Dr. Delorme for a light cuirass to protect the chest and abdomen of the soldier with orders that their action be reported to the Minister of War.

The quality of bread has given rise to universal complaint and has really been the cause of a considerable increase in bowel troubles. The Academy has been examining the question of mixing rice with wheat. It is shown that a kilo of bread costing 70 centimes furnishes 2,500 calories, while a kilo of rice furnishes 3,500 and costs only 50 centimes at most. It is believed that 20 per cent. of rice can be added to wheat in the making of bread without altering its character or diminishing its value. Rice flour is also recommended for thickening gravies, ragouts, and general cooking purposes; the only precaution that should be taken if rice be consumed in considerable quantity is to vary the diet with those aliments rich in cellulose to avoid the constipation which sometimes accompanies a diet of rice.

The American Field Ambulance Corps numbering some 500 men and 250 ambulances which began through private enterprise at the beginning of the war and has been gradually augmented to its present proportions has been absorbed by the U. S.

Army. The men are given opportunity to enlist and continue in the service or retire. This step has been taken following the established policy that all the war activities under American control in France shall come under the direction of the Army or Red Cross as the case may be. So far between 300 and 400 of the men of the Field Ambulance Corps have enlisted to continue service under the American flag.

The historic and picturesque Château de Passy (Passy-sur-Yonne) was the scene of elaborate ceremonies recently on the occasion of the visit of M. Justin Godart, Under-Secretary of State for the Service de Santé, and other officials of the French Government, to the French Hospital of New York, No. 32 bis, which has occupied the château since early in 1915. M. Godart made the trip from Paris to the Passy Hospital to convey his own appreciation and that of the French Government for the splendid work that the administrators and the American personnel have accomplished so quietly and so efficiently for the wounded soldiers of France, and to express that appreciation by the awards of medals to those who have contributed to make it one of the model hospitals of France. The French Minister arrived at Passy-sur-Yonne by automobile at noon, in company with several medical and military officials. He was met at the gate of the spacious grounds by the hospital administrators, M. Henri Chapal and M. André Massénat, the médecin-chef, Major M. C. Culler, of the United States Army, and a delegation of citizens of Passy and officials of the Department of the Yonne. As the members of the party entered the hospital and while they were meeting the hospital personnel an orchestra of soldiers from Sens struck up the "Marseillaise" and followed with the American national anthem.

The concluding ceremony of the day was the presentation of medals. M. Godart began with the announcement that were it not for the diplomatic conventions he would have bestowed upon Major Culler the Legion d'Honneur. As Major Culler is a member of the American Army it would be impossible for him to accept the honor from the French Government. As a result the medal which the major had so well earned would be kept in reserve until such a time as it could be awarded. Dr. John Irwin and Dr. Thomas M. Savage were awarded the Medaille de l'Instruction Publique; Miss Ruby Rodgers, superintendent of nurses, who for twenty-seven months has given devoted and skilled service to the hospital, and Sister Leonore received the silver-gilt Medaille d'Honneur de Dévouement Public, and Miss O'Reilly, Miss O'Connor, Sister Michell, Miss Isabel Adams, Miss Flora Dickson, Miss Anna Crowley, Miss Elizabeth Crowley, Miss Terese Gourley, and Mrs. Grace Wright the same medal in silver or bronze.

Mr. Henri Chapal the Hospital Administrator then told of the origin of the hospital at Passy, its original benefactress, Mrs. William Fitzgerald, and its present supporter, Mr. Henry Walters, of Baltimore. He spoke of the faithful, devoted work of the hospital corps and ended by presenting M. Godart with a bronze plaque, a memorial of the day's visit at the hospital.

4. Dislocations of the Shoulder. — F. F. Henderson states that on examining thirty-two cases of fresh and old dislocations of the shoulder joint with their *x*-ray plates at the Out-Patient Department, Boston City Hospital, it was obvious that the most common complication of the injury is a fracture or a stripping off of the greater tuberosity. Out of these cases examined nineteen showed a fracture of the greater tuberosity three showed fractures through the anatomical neck while the remaining ten showed apparently nothing by *x*-ray. The treatment of these cases is not always an easy one because of the marked inability and obstruction to anything near normal motion. They require a long, tedious course of treatment, the end of which is not always pleasing to the operator. The *x*-ray is of the utmost importance in determining between simple dislocation or dislocation with fracture. The operative cases are those in which a large fragment is torn off and displaced so that the normal position of the arm will not reduce the fragment to a point near that from which it was detached. In such a case the fragment is reduced by open operation held in place by ordinary wire nails. Smaller fragments which are torn off and carried into the joint, where they offer obstruction to motion, are removed by open operation. Exostoses which form as a result of stripping of the periosteum are also removed as above. In all cases where an operation has been performed for removal of obstruction to the outward and upward motion the arm is put up as high as possible and retained in this position by a plaster cast, which should be cut at the end of two and one-half to three weeks, when the patient should receive a slight amount of passive motion, this treatment to be continued from four to five weeks. Fractures without any marked displacement may be treated satisfactorily by the ordinary method of placing the arm to the side, applying a shoulder cap and double sling. The dressing is allowed to remain in this position from two to three weeks when apparatus is removed, and they receive gentle passive motion every third day until the end of the fourth week, when all apparatus is omitted. The operative and nonoperative cases all receive massage and electricity, with passive motion, every other day and are instructed to attempt ladder climbing or slight pulling on a rope above the head. There is still another class in which there is seen no fracture by *x*-ray at the time of injury. Many of these cases are treated as uncomplicated dislocations, but later, in the course of weeks or months, return to the clinic with inability to get anywhere near perfect upward and outward motion. The *x*-ray of such cases usually shows a great deal of thickening about the joint surfaces, with marked proliferation about the greater tuberosity and also an acromion process. Another noticeable change is general thinning of all bones in this region. The treatment of such cases is very difficult because of the long duration and marked proliferation causing obstruction. Such cases should receive a fair trial on ordinary treatment, such as massage, electricity, and extreme passive motion. If satisfactory result is not obtained the arm should be manipulated under ether and put up in extreme extension and plaster and allowed to remain from two to three weeks, then treated as any ordinary operative case, as stated above. In the above cases, by the description of the *x*-ray, it will be seen that there is considerable arthritic change which has taken place, apparently stimulated by trauma. Musculospiral injury in these cases is rather rare, but does occur, and when it does is usually quite promptly relieved by massage and electricity. The nailing of fragments in or near joint surfaces has apparently been followed by no ill effects as regards the motion of the joint.

3. Venereal Prophylaxis.—Henry J. Millstone states that some time ago he pointed out the value of yellow oxide of mercury ointment in the treatment of acute gonorrhea. If there is any reliability in clinical results and laboratory and test tube findings this drug has won a place in the treatment of this disease. The same can be said as to its prophylactic properties. He further states that in the present conflict there is probably no other condition which is lowering the efficiency of men more than the venereal diseases. It is therefore the duty of everyone who has worked along these lines to submit to the government such information and suggestions which might be of some help in controlling, if not in completely eradicating, this scourge. He does not claim originality for the suggestions submitted here, but merely plea for a fuller recognition of the facts presented. The value of mercury in the prophylaxis and treatment of syphilis is familiar to all. While teaching soldiers of the dangers and detrimental effects of immoral indulgence is of great value still it must be admitted that this point only appeals to the minority. Regardless of how strongly we may impress the fact that the sexual act is not a necessity for the maintenance of life and good health it will take more than weeks and months to prove that it is not a necessary evil. In approaching these men we have the same problem to contend with that we have with drug addicts: most of them do not want to be cured. Most of our soldiers do not want to stop "partaking of the bitters." It will take a war greater than the present conflict to eradicate this evil for it is not a war of man for man, but a war within himself—that is, will power against passion. We may pitch these men's minds to a point where they will swear by all that is holy, "Never again!" but no sooner are they thrown into temptation than they again enact the role of a "fool there was." We who are devoting our time to genitourinary work have the facts at hand. One would think after a man had been burnt once that he would know enough to keep his hands out of the fire, and all of us can recall offhand many a patient who has taken upon himself more than one infection. It is reasonable to suppose that while issuing pamphlets denouncing sexual abuses and preaching these lessons is going to do some good, yet we will fall far short of meeting the problem if we stop at this point. There is no need to shield the naked truth or clothe these facts in mystery. There has not been enough preliminary work to hope to solve this problem. It will require a greater enlightenment of the subject, aided by sex hygiene and eugenic laws—a greater education along these lines not handed down by experience but begun in the lower grades of school. It will require the abolition of house and street prostitution. It will be the duty of every father and mother to present to their sons and daughters these very important essentials and not to keep this information from them as they would a hidden treasure. Millstone considers that while many of these ideas have been launched still they have not been in existence long enough to have any bearing on the present situation. At present there is much controversy among the various factions as to whether or not a deck of cards and smoking tobacco should be put into the soldier's kit. Millstone suggests that each man should be equipped with a tube of 2 per cent. of yellow oxide of mercury ointment, and he considers that there will be nothing that the soldier will carry that will be of greater benefit not only to himself but indirectly to his country. Along with this he should be given a booklet the contents of which should picture to him the aftermath of these abuses in all their hideousness. Herein at least lies a part of the solution for the control of this great plague. And still it must be remembered that "a man's a man for a' that."

2. The Menace of Mouth Infections.—Oliver T. Osborne considers that there is not a greater menace to health today than crowned and bridged teeth, to say nothing of imperfectly filled and dead teeth and of pyorrhea alveolaris. Infection of the tonsils and the sinuses adjacent to the nose must never be overlooked, and eradication is the only safety. From infected areas in the mouth many pathogenic organisms have been isolated, probably the most dangerous being the pneumococcus and the *Streptococcus viridans*. In a reference to the treatment of pyorrhea alveolaris Osborne emphasizes the fact that dentists use iodine too freely on the gums. A little pain here or a little infection there and the gum is injured by repeated applications of iodine. He further states that one of the saddest things that can happen to a person is infection of the blood with the *Streptococcus viridans*. In the vast majority of cases the only hope for the patient with this infection is to eradicate it from the mouth before it infects the blood and causes malignant endocarditis. Cooperation between physician and dentist is necessary in the handling of these cases. The relation of mouth germs to arthritis deformans seems proved, hence eradication of the source of infection before the joints are affected should be the preventive treatment of today. Osborne draws the following conclusions from the results of study and work with cases of mouth infections: (1) Most unexpected tolerance to pyorrhea alveolaris and to tooth infection is found. (2) Chronic invalidism may be caused by mouth infections. (3) The blood pressure may be raised or lowered by mouth infections. (4) The thyroid gland is frequently enlarged, and may hypersecrete or hyposecrete in these infections. (5) Serious disturbances of the blood, heart, kidneys, stomach, intestines, and joints are frequent from mouth infections. (6) Glycosuria can be, and perhaps true diabetes mellitus may be, caused by mouth infections. (7) Serious distant focal infections may occur from mouth infection. (8) Serious brain and nerve disturbances, as well as neuritis, may occur from mouth infection. (9) Ulcer of the stomach, pyelitis, appendicitis, and chronic colitis may be caused by pyorrhea alveolaris and mouth infection. (10) Pneumonia, especially that which follows influenza, may frequently be caused by pneumococci long carried in the patient's mouth. (11) No treatment of these conditions will be of any avail until the mouth is made clean. (12) Stock or autogenous vaccines are not very promising as to their therapeutic value, but in obstinate cases they should be tried. Therefore it is generally well to grow a culture from the infection in the mouths of these patients, that autogenous vaccines may be made and used, if desired. (13) One should be very careful not to promise a cure of a distant condition, although that condition was caused by the mouth infection. However, many brilliant cures are caused by surgical eradication of infected areas. The patient should always be told that the surgical removal of the infected area in the mouth does not remove the germ localized in distant parts of the body, nor does it immediately cure an inflammation caused by these germs in a distant part, nor will it restore degenerated tissue, but it will remove the primary source of infection. (14) It should be urged that any

fresh lesion of the mucous membranes of the mouth is a source of danger, much as is a lesion of the skin. The efficiency of the integument in warding off disease germs has long been recognized. It should be recognized that fresh cuts, abrasions, and blistering of the mucous membrane of the mouth with iodine or other strong escharotics offer the opportunity for the absorption of germs that may be freshly received into the mouth, and more especially of germs already in the mouth.

3. The Occurrence of Spirochætes in the Urine.—James L. Stoddard says that a widespread interest in the increasingly numerous group of diseases known to be caused by spirochætes, and the consequent desire for a rapid and sure means of diagnosis, have brought forward the possibility of recognizing such cases by finding the spirochætes in the urine. He further states that by investigation he has found that (1) spirochætes are not uncommon organisms in the urethra of men without history or symptoms of relapsing fever. (2) Many different varieties are found. (3) Some of the varieties seen are morphologically closely similar to pathogenic varieties. (4) The spirochætes occur so definitely within the urethra that they are an obvious source of contamination in uncatheterized specimens of urine. (5) They are a sufficiently dangerous source of error, even in catheterized specimens, to deserve attention in careful work. (6) It is possible that a staining reaction or some other morphological character may be discovered to differentiate microscopically the common and harmless from the pathogenic spirochætes. Since the pathogenic spirochtæes are still in the process of discovery, such methods are not universally applicable. The facts summarized above are possibly known to a few workers, but they are not to be found in the publications at our disposal. They are new to us, and probably to a majority of those who are likely to make use of them. That a source of error in diagnosis may be pointed out, and possibly time saved for prospective workers in these diseases, the observations made are given herewith. He summarizes the results of his investigations as follows: A series of 100 men without history or symptoms of relapsing fever showed intraurethral spirochætes in 33 per cent. of the cases. If spirochætes of the *refringens* type are included, the incidence rises to 44 per cent. The spirochætes occurred in about one in two and one-quarter men sick of miscellaneous medical and surgical conditions, and in one in five of healthy men. This difference is probably to be ascribed to differences in hygiene, and to the variations in amount of flora of mucous surfaces familiar in other regions, in conditions of varying vigor. The variety of organisms makes it improbable that the mere finding of spirochætes in the unine can have any diagnostic value in relation to the relapsing fevers until definite morphological or other differences are established between the various normal and pathogenic varieties.

4. Spirochætes Occurring in the Urine of Cases of "Pyrexia of Unknown Origin."—S. W. Patterson states that during the past few months he has examined the urine of cases of P. U. O. (pyrexia of unknown origin) for spirochætes, using a modification of Renaux and Wilmaers' technique. The results are so suggestive that he offers this preliminary note to call attention to the necessity for the systematic examination in certain clinical types of P. U. O. which may ultimately turn out to have a common etiological origin. Since in March, 1917, Garnier and Reilly suggested that in certain cases of icterohemorrhagic spirochætosis the chief incidence of the disease may be upon the kidney, he has examined a number of cases of trench nephritis and found a spirochæte in a fairly large proportion. Further, in what he regards as a definite clinical type of P. U. O. (appendicular, or abdominal—described below), which is probably a mild form of icterohemorrhagic spirochætosis, he has found a spirochæte almost constantly present in the urine. Again, in the relapsing type of P. U. O. (trench fever) a spirochæte can frequently be found in the urine during and immediately after the exacerbations of temperature. Upon examination of the urine by the above-named method the spirochætes are shown to have the following characters: They are about one to one and a half times the diameter of a red blood corpuscle, and are very thin, the ends tapering. They show five to eight more or less regular turns, and may be straight, bowed, or lying in a semicircle. The spirals are not so fine as in *Spirochæta pallida*, nor so coarse as in the spirochæte of Obermeier. The organisms are very resistant to staining, being uncolored by Leishman, Romanowsky, or Giemsa's stains, and requiring a mordant method, but may be demonstrated by India ink methods. They occur in the urine, often abundantly, during and immediately after the rise of temperature, but in the intervals may be so scarce as to be practically absent. Like McNee and others, he has been unable to find any organism by direct examination of the blood of these patients, and he has not had an opportunity of determining post mortem at what part of the urinary tract the spirochætes originate. These observations suggest that at least two clinical types of P. U. O. may be brought into line. (1) a disease with acute onset with chills and vomiting, pain in the abdomen, usually more marked in the right upper quadrant, with continued fever for several days, often with enlargement of the spleen and herpes of the lips. The pulse-rate is not increased, and is usually slowed to 50 or 60 beats a minute in convalescence. There is a leucocytosis of 12,000 to 25,000 with relative increase in the large mononuclears. The cases, if an attempt is made at diagnosis, come to the base as "? appendicitis," or "N.Y.D. abdominal"—the initials "N.Y.D." standing for "not yet diagnosed." He recognizes that these are the cases which presented nothing but abnormal temperature, malaise, and slow pulse, and were evacuated to England. French authors have suggested that cases of icterohemorrhagic spirochætosis may have almost their whole incidence upon the kidney, and so one finds spirochætes in cases which cannot be distinguished from acute (trench) nephritis, except perhaps by the long continuance of much albumin and kidney débris in the urine. (2) The relapsing type of P. U. O. (trench fever) with the characteristic periodic rises of temperature, myalgic and periosteal pains, and leucocytosis with or without enlargement of the spleen, in which an improving technique has enabled him more and more frequently to find a spirochæte in the urine during and immediately after the exacerbations of temperature.

7. Notes on Ionic Medication and the Method of Administration.—Leighton Kesteven states that from the incontestably satisfactory results obtained by ionization as compared with simple electrolysis, he thinks it is impossible to doubt that ionic penetraton takes place. His experience in the treatment of ear disease has given him results that he could hardly have obtained by any other method. Resolution of inflammation, release of adhesions, and general bactericidal action are the things to be aimed at in dealing with the ear. Galvanism has done some good, but the great value of ionization lies in its sclerolytic effect. The absence of satisfactory results is somewhat due to the insufficiency of the technique employed. The proper method for treating the tympanum is to lay the patient's head sideways on the table, and to fill the external meatus with the solution employed, then the current is passed through it, thus ensuring a constant supply of the required ions. A small probe insulated to its tip will carry the current into the solution. Great relief may be obtained in classes of middle-ear catarrh in this way by the use of a solution of zinc iodide (30 per cent.) with 3 to 4 milliampères of current. Zinc iodide is a colorless and stable compound made by boiling zinc and iodine together in water in the proper proportions. It is nonirritative and soothing in action. Iodine being an

anion and zinc a cation the current must occasionally be reversed to get the benefit of both the elements, removing the anode during reversal to avoid the shock. In acute cases the current may be kept on for five to ten minutes, in chronic for twenty. The relief of pain in the acute cases is very marked after the current has run for a few minutes. In more recent cases relief comes speedily, a half dozen applications may suffice; in those of long duration weeks, and even months, are called for, and it is never justifiable to call off treatment without prolonged trial. In the functional deafness caused often by nerve exhaustion, the result of mental trouble, ionization gives much relief, often acting like magic. Many mastoid cases, if taken at a reasonably early stage, can be arrested and operation avoided by ionization with an absorbefacient bactericide. Mercuric iodide presents such a compound, and can be administered in 1 to 500 solution for periods of half an hour morning and evening with 5 milliampère current. Ionization with a 2 per cent. solution of alum is useful in relaxation of the tympanum. Kesteven has used arsenic ions in two cases of tuberculous middle-ear disease; in one case without result, in the other with very marked benefit. Aural vertigo so often indicative of labyrinthine loss of couple, is generally, but slowly, relieved by the mixed continuous ionization and mild faradic current. Labyrinthine tinnitus can also be greatly relieved and often removed by iodine ionization. The positive pad should be placed behind the mastoid, and the current (5 milliampères) sustained for half an hour on alternate days for a week or so. If pain is at any time urgent immediate relief can be given by ionization with cocaine. Morphine will act similarly, but more slowly. Goiter has been tackled with varying success by radium and *x*-ray therapy. It yields to ionization in a satisfactory manner, but the treatment is long and tedious. Kesteven employs this method of treatment for acute tonsillitis, using a curved aluminum probe insulated to within half an inch of its end, round which cotton-wool is wound and dipped frequently in 5 per cent. zinc iodide solution, and a 15 to 20 milliampère current is passed through the tonsil for five to ten minutes. Relief from pain is speedy, and the tumefaction subsides so rapidly after the applications that the tonsil will be nearly its normal size within forty-eight hours after the first application. Two or three applications are usually sufficient. In chronic indurated cases longer treatment is called for, say eight or ten times on alternate days with a 10 per cent. solution. The negative current should be passed through the probe, as iodine is an anion, and a padded cathode placed at the back of the neck. Enlargement of the turbinates can be reduced by the zinc iodide, but only 2 per cent. solution should be used, and about three minutes at a time is all that should be given, and a carbolic powder should be blown in afterwards to allay any smarting. The Eustachian tube can be ionized with a Eustachian catheter perforated at the sides for the last quarter-inch, and closed at the end. This is connected to a fine tube holding the ionizing fluid, with a fine wire in it to carry the requisite 3 milliampère current. It is best to use potassium iodide, as the zinc might do harm if swallowed. Five minutes at a time is ample and will often relieve middle-ear tinnitus. Enlarged prostrate can be treated with success by this method. Either aluminum or copper wire an eighth of an inch thick can be used for the probe electrodes, and an easy way to insulate them is to dip them into a saturated solution of celluloid in acetone. The points can then be scraped bare with the knife for the cotton-wool at the ends. The celluloid will not bear boiling, but can be sterilized with 30 per cent. carbolic solution.

Functioning of the Adrenals in Infections Conditions.—Goormaghtigh contributes a preliminary note on this subject. He has studied 70 autopsy specimens obtained from a quarter hour to an hour after death from hospital patients dead of infections. Those who inspect the adrenals systematically during autopsies are familiar with two general types, normal and pathological. The latter presents a much smoother surface, of a frankly red color and sometimes brownish and even sepia. The consistence and weight are both increased. On section the medulla shows little or no change, but the cortex is profoundly altered. It is much thicker, and is uniform in texture, the yellow layer having disappeared. This type is present in all infections. The histological appearances are described in great detail and tend to show that in infectious states adrenaline is produced in excess, and that this excess of labor sometimes ends in exhaustion. Does the injection of adrenaline tend to activate the adrenals or does it only add to the blood a substance which is deficient? The examinations show that in those patients who received adrenaline injections during their illness the functional activity of these bodies was augmented. To obtain this result the drug must be injected subcutaneously in frequent (daily) doses. The material studied by the author consisted of surgical infections such as complicate war wounds. The author purposely avoids touching upon degenerative processes in the glands. The functional activity is alone considered. While the medulla activates the production of adrenaline, the cortex exerts an antitoxic power in infections through the production of certain lipoids. The adrenals and ovaries represent the chief sources of cholesterine, and indeed these two sets of organs resemble each other remarkably in several ways. The changes described by the author are purely functional and not to be confounded with any form of organic disease.

Traumatic Asthma.—Loeper and Codet refer to the dyspnea which so frequently follows traumatisms of the chest. This may persist for a long time and be either continuous or paroxysmal. It may have a mechanical, nervous or reflex mechanism, may be spontaneous or determined by an effort. It may simulate asthma closely, and this is the clinical expression to be considered here. This is rare in comparison with dyspnea proper, and it has been recorded but 5 times after 200 cases of traumatism of the thorax. Two cases are related, one of which is as follows: A sergeant received a penetrating wound of the thorax, in which a shrapnel bullet entered at the right clavicular region and emerged on the left side, at the scapulo-vertebral region, fourth intercostal space. The patient suffered from hemorrhages, frequent cough, fever and purulent expectoration, which symptoms lasted 5 or 6 weeks. Then when he seemed to be well he was seized with a paroxysm of asthma which necessitated his removal to a hospital. The paroxysm consisted of a short inspiration and a prolonged and difficult expiration with thorax distended. This crisis lasted 18 or 20 hours, during which patient sat up in bed with lips cyanotic and eyes overflowing with tears. He was constantly nauseated, vomited on occasion, and was also bothered with hiccough. The pulse was between 66 and 80, and compression of the eyeball lowered this rate to 30. As soon as the patient was able to expectorate freely the attack was evidently over. The crises appeared every 2 or 3 days, and after a crisis ocular compression lowered the pulse to 12. Radioscopy did not discover any sclerotic process, and sputum examination was negative. The second case closely resembled the first.

Syndromes Due to Gas Intoxication.—Voivenel and Martin, as a result of analysis of a number of cases of gassing, classify the material as follows, leaving out cases that perish at once as if drowned. Cases in which there is survival may be grouped as follows: Very severe, severe, and moderate or mild. In the very grave type we have a dominant and an exceptional form. In the former patient is cyanotic, with intense dyspnea and foamy saliva. The condition is one of subacute pulmonary edema. Despite the alarming condition, remarkable results are obtained from ipecac, venesection, and oxygen. In the exceptional form the patient is livid. The condition appears to be one of disturbed function (so-called form *sine materia*). In all very severe cases suprarenal insufficiency is in evidence. The patients are comatose, half comatose, torpid, mentally confused. The severe type, as distinguished from the very severe, suffers from marked

dyspnea, incessant cough, occasional vomiting; it differs from the very severe form in degree only. Finally the mild and moderate cases exhibit three clinical forms, viz.: pulmonary, gastroenteric, and nervous. The latter alone requires mention. It appears in the predisposed, and is expressed chiefly as pain and nervous and muscular asthenia, the pains comprising chiefly headache and backache.

Is There a Closed Type of Tuberculosis in Evolution?—Richet Junior believes that pulmonary tuberculosis in evolution is always "open," from the very outset, and that the sputum always contains bacilli, and is contagious. The general belief is that in a large fraction of cases of clinical tuberculosis the sputum is bacillus-free, because the foci are "closed." Opponents of this belief have not been numerous, but of late some notable authorities have reached the opposite conclusion—Bezançon and de Jong and Rist for examples. This does not mean, perhaps, that the sputum is never free from bacilli, and in any case it is often necessary to use technical refinements to reveal their presence. One-slide tests are utterly untrustworthy. When a number of smears are made some of them will be negative. With physical signs of apex tuberculosis the first question relates to age. Is the focus old and stationary or recent and progressive? If the latter is the case, bacilli will practically always be found in the sputum. On the other hand, physical exploration may be negative throughout and yet there may be sputum containing the bacillus. A case is cited of a man who exhibited all the phenomena of healed tuberculosis, including absence of bacilli in the sputum. A week later a second sputum test made with all refinements of technique proved positive, much to the surprise of the medical staff. In another case the same sequence was present, with a single bacillus in the smear. Further tests, however, were negative, coinciding with disappearance of expectoration. Cases of this type are not uncommon and tend to show the limited value of negative finds. If, however, the latter persist, we may feel sure that the patient is improving. A certain number of negative finds has the same value as a single positive find. The fetish of a closed progressive tuberculosis of the lungs has come about perhaps from our knowledge of lymph node and bone tuberculosis, for here the surgeon, speaking surgically, can properly speak of open and closed lesions. There is no warrant at all to transfer this dichotomy to pulmonary lesions.

Intranervous Injections of Alcohol in the Treatment of Causalgia.—Pitres and Marchand describe three cases of atrocious suffering due to injuries of nerve trunks in which alcohol was injected above the lesion. In one case reported at length not only was the pain cured but motor and trophic disorders as well. The subjective sensations were those which attend upon severe burns. Neurolysis of the median had been without relief when the alcohol (60°) injected into the exposed trunk gave instantaneous relief. In another case due to injury of the medius a negative, and in a case of causalgia associated with paresis in the sciatic nerve area a positive results were forthcoming. The chief fear that interrupting the efferent nerve impulses can cause or increase motor paralysis is shown to be unwarranted.

Correspondenz-Blatt für Schweizer Aerzte.

September 1, 1917.

Frequency of Miliary Tuberculosis in Old Age.—Braun gives figures from the Pathological Department of the Basle University which show that over 14 per cent. of all cases of miliary tuberculosis were present in cadavers of subjects above the age of 60 years. This refers only to acute general miliary tuberculosis which must necessarily have developed late in life and have been the essential cause of death. The lungs were involved in practically every case, a fact previously noted in connection with this affection, and due to the fact that the bacillus enters the circulation through the venous system and encounters the lungs immediately through the lesser circulation. In old age it is even more apt to be arrested here than in earlier years. Next to the lungs in frequency the kidneys, spleen and liver are involved to a greater or less degree, and in a good majority of cases. The meninges are but rarely attacked—in about 10 per cent.—in direct contrast with the frequency of this participation in youth. The choroid shows an even greater degree of immunity; in fact, save for the lungs and other viscera first mentioned, all the tissues show more or less immunity. The mechanism of the infection is not readily apparent. Old foci were found in lymph nodes, lung tissue and other localities, and in about one-half of the cases a solitary focus of old tuberculosis could be held responsible. In the remainder there was more than one focus involved in the process. Vascular lesions, usually occurred in these cases as responsible for general infection, are not mentioned (save for a certain number of cases in which the thoracic duct was primarily involved). In explanation it should be stated that the autopsy material goes back to 1872, so that for many years vascular tuberculosis was not looked for. In its absence we can only attribute the majority of the cases to old lesions in the lungs and lymph nodes. The diagnosis of acute general miliary tuberculosis in old age is very difficult to make. Paradoxical cases of bronchitis and bronchopneumonia with signs of heart failure doubtless usually conceal its presence.

Glas's Symptom in Acute and Chronic Suppuration of the Nasal Sinuses.—Oppikofer refers to Glas's announcement in 1911 of a new diagnostic procedure in which a tuning fork was applied (as in Weber's method for otitis) with the presumption that the patient's hearing was normal. The method was to be of use to the general practitioner, in the absence of a rhinological examination. It should furnish a means of controlling the condition throughout, informing us as to progress of the case under treatment. But in using Glas's method we have to take the patient's word in arriving at a conclusion, and, further, no information is given as to the exact source of the pus (perhaps one of the other sinuses). Two men have in a way corroborated Glas's findings, but an authority like Hajek does not even mention the test in his edition of 1915. The author and his chief, Siebenmann, have examined 69 cases in the Basle nose clinic by Glas's method. All were adult patients with intact hearing apparatus. There were 21 cases of acute and 41 of chronic unilateral empyema of the antrum. In the latter class other sinuses were in part involved. The other 7 case were bilateral. In but 4 cases was a positive result forthcoming. The test is then worthless, and the only point of interest is the manner in which it imposed itself on three trained specialists. The underlying law is the superior conductivity of liquids and solids over air. Hence a tuning fork on the median line of the skull would have a superior conduction on the side in which the antrum contained fluid and thickened mucosa, and the patient would lateralize the sensation, as in Weber's test for inflamed middle ear. To obtain such results as he did Glas must have powerfully influenced the patients' answers by his mode of questioning.

The New Edema Disease.—Lange describes this new and peculiar affection which occurs chiefly in women in West Germany. Polyuria and nycturia are marked but bradycardia is not mentioned, nor is there any allusion to cachexia and a fatal outcome. Apparently there is more than one species of edema disease. In Lange's material there was no apparent physical cause. The organs seemed quite sound. The victims lived almost wholly on carbohydrates, the diet being calcium poor. This may have brought about a state of hydremia.—*Nederlandsch Tijdschrift voor Geneeskunde.*

Results of Continuous Low Neck Wear in Women.—Brocq states that as the result of going bare chested for 3 years women have developed an integument of very peculiar texture, with diffuse and lenticular pigmentation, telangiectasis, coarsening of the skin, keratosis of the follicles and acne. This does not include sunburn and its sequelæ. The resistance of the skin to disease is also much lowered as shown by the frequent development of eczematoid eruptions.—*Annales de dermatologie et de syphiligraphie.*

Book Reviews.

HANDBOOK OF GYNECOLOGY FOR STUDENTS AND PRACTITIONERS. By HENRY FOSTER LEWIS, A.B., M.D., Professor and Head of Department of Obstetrics and Gynecology in Loyola University School of Medicine; Chief of Obstetric Staff of Cook County Hospital; Fellow and Ex-President of the Chicago Gynecological Society; Late Assistant Professor of Obstetrics and Gynecology in Rush Medical College (in Affiliation with the University of Chicago), and ALFRED DE ROULET, B.Sc., M.S., M.D., Professor of Gynecology in Loyola University School of Medicine; Attending Gynecologist to the House of the Good Shepherd, and to St. Bernard's Hospital; Obstetrician and Chief of Staff of St. Margaret's Home and Hospital. Octavo of 452 pages, with 177 illustrations. Price, $4.00. St. Louis: C. V. Mosby Company, 1917.

THIS book is designed primarily for the third and fourth year medical student and the young practitioner. The authors say that they have tried to appreciate that gynecology is a lesser subject than medicine, surgery or obstetrics, and have tried to prepare a book which will recognize, in its demands upon the time and energies of the student and reader, the proper rank of the specialty. Long descriptions of major operations and their technique have been omitted, and the authors have endeavored to formulate principles of surgery adaptable to the special work without elaborating minor details. As they say, one cannot learn technique by reading descriptions and studying illustrations. In their opinion the primary requisite is a good foundaton in pathology, anatomy and physiology; next, practice in assisting good operators at the bedside and at the table.

The authors' method of handling their subject is somewhat unusual since they have followed, as far as possible, the lines of pathology rather than the usual anatomic method, which consists in taking up the lesions of individual portions of the genital tract from vulva to Fallopian tubes. Thus, in this book gonorrhea, in all its aspects, is discussed in one chapter in which is covered both the immediate and remote results of gonorrheal infection in all the various parts of the genital tract. From the initial chapter on the anatomy and physiology of the female genitals to the last, covering neuroses and psychoses, the book is full of meat. The chapters covering what might be called general considerations, such as those on diagnostic methods, asepsis, care of the patient before and after operation, and anesthesia are excellent, and filled with what might be termed in the vernacular "good horse sense"; while the authors have covered all the special fields on the same preëminently rational basis.

A MANUAL OF ANATOMY. By HENRY ERDMANN RADASCH, M.Sc., M.D., Assistant Professor of Histology and Embryology in Jefferson Medical College; Instructor in Anatomy in the Pennsylvania Academy of Fine Arts, Philadelphia. With 329 Illustrations. Price, $3.50 net. Philadelphia and London: W. B. Saunders Company, 1917.

THE author of this volume is to be congratulated on his courage in breaking away from the tradition that a book on anatomy must be the largest volume on a student's bookshelves. It has long been evident that a work intermediate in size between the present textbooks and the compends might supply all that the average medical student requires. The present volume attempts to supply this want, and should be welcomed by beginners, premedical students and nurses. The main facts of anatomy are well presented, and most of the comparatively unimportant details are omitted. The book is well printed and illustrated, most of the illustrations being taken from standard works. It is an excellent short textbook on the subject, and should soon become popular with the class of readers for whom it is intended.

SANITATION FOR MEDICAL OFFICERS. By EDWARD B. VEDDER, M.D., Lieut. Col., Medical Corps, U. S. A. Illustrated. Price, $1.50. Philadelphia and New York: Lea & Febiger, 1917.

THIS is the first of the medical war annuals, authorized by the Secretary of War, and brought out under the supervision of the Surgeon General and the Council of National Defense. It is peculiarly appropriate that the first of the national medical war annuals should be devoted to sanitation. In no war has preventive medicine played so great a part as in the present war, and it is mainly due to effective sanitation that epidemic disease on a large scale has been prevented among the armies in the field. Col. Vedder has produced a manual worthy of his reputation as a sanitarian, and this little work should prove of the greatest value to medical officers.

PRINCIPLES OF PHARMACY. By HENRY V. ARNY, Ph.G., Ph.D., F.C.S., Professor of Chemistry in the College of Pharmacy of Columbia University; Sometime Dean and Professor of Pharmacy in the School of Pharmacy of Western Reserve University; Member of the Committee of Revision of the United States Pharmacopœia, Ninth Revision; Member of the Committee of Revision of the National Formulary, Fourth Edition. Second Edition, Revised; with 267 Illustrations. Price, $5.50 net. Philadelphia and London: W. B. Saunders Company, 1917.

THE first edition of this book appeared some eight years ago; in the meantime considerable advances have been made in chemistry and pharmacy, and new editions of the United States Pharmacopœia and the National Formulary have been issued. As a result, a large number of changes will be found in this new edition. The general plan of the book remains as before, and the author is to be congratulated on having reduced the bulk of the volume. The book consists of seven parts; the first deals with pharmaceutical processes; the second, with galenical preparations; the third and fourth, with the inorganic chemicals used in pharmacy, with chemical theories and chemical arithmetic; the fifth, with chemical testing; the sixth, with the prescription; while the seventh gives an outline of laboratory work, with exercises in equation writing and in chemical arithmetic. An important feature in this new edition is the insertion of a carefully selected bibliography at the end of several of the more important chapters. The book will prove an interesting and valuable addition to the working library of every physician.

DREAM PSYCHOLOGY. By MAURICE NICOLL, B.A., M.B., B.C. (Camb.), Capt. (Temp.) R.A.M.C. Price, $2 net. London: Henry Frowde, Hodges & Stoughton, Oxford University Press, 1917.

TEN years ago we doubt if such a book as this would have been taken seriously even. Freud and his followers have endeavored to dignify the dream by labeling it a significant product of the unconscious, and even their detractors are forced to give attention to its possibilities. The present volume is Jung rather than Freud, and in some instances it does not appear that Jung is accurately interpreted, particularly where emphasis is laid on the process of the dream over-compensating or under-compensating conscious ones. Introversion and extroversion are competently expounded. As a whole, Dr. Nicoll's book is a well-written, extremely suggestive treatise on the dream.

CLINICAL CARDIOLOGY. By SELIAN NEUHOF, B.S., M.D., Visiting Physician, Central and Neurological Hospital; Adjunct Attending Physician, Lebanon Hospital. Price, $4. New York: The Macmillan Company, 1917.

IN this work Dr. Neuhoff has paid especial attention to graphic methods in the study of heart disease rather than to instrumental and technical considerations. Moreover, he writes more from the clinician's than from the cardiologist's standpoint. The author is somewhat inclined to deprecate the fact that so great importance is given in recent books on cardiac disease to instrumental methods, for while recognizing their importance, he is yet of the opinion that these are not infrequently subsidiary. Consequently, a considerable part of the book has been devoted to the clinical side of cardiology, and the subjects of pathology, etiology, diagnosis, prognosis, and of the therapy of endocarditis, myocarditis, and cardiosclerosis are accorded full consideration. The work is well illustrated and will be found to be an exceedingly useful book of reference.

Society Reports.

AMERICAN PUBLIC HEALTH ASSOCIATION.

Annual Meeting Held in Washington, D. C., October 17-20, 1917.

THE meeting of the American Public Health Association, held in Washington, D. C., from October 17 to 20, was a war meeting and most of the discussions and papers referred to topics directly or indirectly connected with the prosecution of the war. The outstanding feature of the meeting was the mutual desire for cooperation on the part of the military and civilian medical public health workers. The old-time self-satisfied attitude of the army medical men has given way to a whole-hearted appreciation of the advice and help from outside agencies. This keynote was voiced in all of the addresses and speeches made on behalf of the Army and Navy.

Triumphs of Sanitation.—Invariably, also, the triumphs of sanitation over the previous scourges of war were emphasized. In 1898, during the Spanish-American War, the American army had approximately 22,000 cases of typhoid fever with about 2100 deaths, most of the infections occurring in the United States; in 1916, when a similar number of soldiers were encamped on the Mexican border, there were only 46 cases of typhoid with one fatality, this single death being the case of an officer in the Medical Reserve Corps who claimed to have had typhoid fever and consequently did not take the anti-typhoid vaccination.

Likewise, scurvy in the naval forces has been almost exterminated. Surgeon General BRAISTED of the Navy gave an account of the decrease of scurvy in the last one hundred and twenty-five years. He stated that in 1797, prior to the introduction of anti-scorbutic measures in the British Navy, the death rate was approximately 120 out of every 1000 per annum. Fifty years later the rate in the British Navy was 30 per 1000 and last year in the American Navy the loss was but 4.48 per 1000 of personnel. This is one of the conspicuous examples of sanitary achievement in the Navy. The provision of cold storage facilities on the ships for preserving fresh vegetables, fruits and meats, the installation of good ventilation, lighting, and plumbing, the establishment of hospitals and the general care of the health and comfort of the mariners has made the American Navy unexcelled in general health standards and sanitation. The healthfulness of the navy is remarkably good.

Venereal Diseases.—One of the most seriously debilitating influences in the Army, as well as in the Navy, is venereal disease. The prevalence of venereal infection, as is well known, has been very large in the regular army, over 90 per 1000 men suffering from these diseases. It is most astonishing that the recently drafted citizen army contains more than twice as large a percentage of venereally infected. The rate is something like 212 per each 1000 men. Venereal diseases, for obvious reasons, were not a cause for exemption from military service. Dr. R. C. HOLCOMB, medical inspector of the Navy, spoke at length about venereal prophylaxis. It failed to a large extent because of the ignorance and indifference of the men and the indulgence in alcohol. In spite of the efforts made through education leaflets and talks to inculcate into the minds of the men the dangers of venereal disease and the importance of early application of prophylactic measures, the results have been discouraging. A study of 32,852 cases revealed the fact that a monthly percentage of men who took prophylactic treatment varied all the way from 2.06 per cent. to 59.9 per cent. On one ship where the prophylactic tubes were carried in the canteen for sale, just 7 tubes were sold from September 10 of one year until February 4 of the next. In view of such ineffective use of the packet, a law of punitive prophylaxis went into effect on August 29, 1916, which provides for the stoppage of pay because of absence due to sickness caused by venereal diseases, and this measure is considered by Dr. Holcomb as one of the most effective methods of meeting indifference. The following are the statistics to bear out his conclusions: For chancroid the daily sickness admission rate for the first three-quarters of 1916 was 6.68 and for the last quarter of the year (after the law had gone into effect) it was 6.45. The average time lost during the first three-quarters was 35.91, and for the last quarter it was 33.58 days. For gonorrhoea, the daily admission rate showed a decrease for the same period from 16.17 to 14.11 and the time loss from 132.89 to 84.11 days. For syphilis, the daily sickness admission rate increased from 4.15 to 4.38, but the time lost decreased from 217.46 to 172.64 days. It has been suggested that punitive prophylaxis may have the result of making men avoid going to the medical officer for fear of losing their pay and that in the long run more harm will come from it than good. Dr. Holcomb, however, argues that the figures showing the decrease in time lost do not bear out this fear.

Dr. Gorgas may have presented the case a little too strongly when he stated that disabilities from wounds in war time do not exceed the disabilities from venereal diseases, but this statement drove home to his listeners the magnitude of the problem.

Military Statistics.—The amount of time lost because of sickness and injuries in the army in ordinary times may be gauged from the statistics given by Col. WESTON P. CHAMBERLAIN of the Medical Corps of the Army, The total number of admissions to sick report is ordinarily very high. It was 726.19 per 1000 men for the year 1915. For the year 1914 the average was 660.45. The annual death rate per 1000 men in the Army for the decade from 1905 to 1915 was 5.17 and the discharge rate per 1000 for the same period was 16.81. The average rate of constant sickness or the so-called constant non-effective rate was 23.78, and the average number of days lost per year by each soldier because of sickness was 8.77. This rate includes disabilities from injuries as well as from sickness. Both Dr. Chamberlain of the Army and Dr. J. R. Phelps of the Navy gave detailed descriptions of the health and hospital records kept in the two branches of the military establishment of the United States. The Army records enable us to obtain the extent of sickness and injury by days and weeks and also to get full knowledge of each specific disease and injury according to age and length of military service, rank, branch of service, race and color, geographical divisions, and climate. The importance of carefully kept sickness statistics of the Army and Navy cannot be overemphasized.

Mental Disorders.—Systematic and well planned care of mental and nervous disorders occurring in the Army is a new feature of the medical organization of our military service, devised under the enlightened leadership of Dr. Gorgas. Major PEARCE BAILEY discussed this phase of the medical problem and called attention to the large number of cases of nervous and mental diseases developing under the strain of modern welfare. The first statistics ever accumulated concerning this phenomenon were collected during the Russo-Japanese war, and from this source we learned that 1700 cases of these disorders resulted from the siege of Port Arthur. When the present war started neither France nor England had made any provision for the care of the large number of nervous and mental cases and they soon began to realize the need for reconstruction of their medical organization. As a result a large number of psychiatrists and neurologists were called into the army. The English statistics were reported to show that one-seventh of all discharges are due to nervous and mental disability, while wounds produce only one-third of all the discharges. The medical organization of our army has, from the outset, taken cognizance of the existence of these conditions. Provisions have been made for the elimination of the unfit and all those likely to break down from nervous causes under war strain and for facilities to care for those who, in spite of all precautions and selection, might become afflicted. The men suffering from mental and nervous defects such as epilepsy, psychoses, and syphilis of the central nervous system, are exempted from service in our army. The records already available show that from 1.5 to 5.0 per cent. of the troops examined have been discharged for these causes. The fighting morale of our army will be greatly strengthened by the elimination of this type of cases and the special hospital provisions which are being devised for taking care of nervous and mental

cases will prove of inestimable value to our troops.

The Food Problem.—The question of food and its relation to the war was under consideration. Mr. HERBERT C. HOOVER presented a statement of the magnitude of the problem of supplying four principal staples to our Allies on the firing line. The foods selected for shipping abroad are those which contain the most food in concentrated form, such as meat, sugar, grain, and dairy products. He stated that sixty million bushels of grain every month are required for export. Our wheat crop this year is below par, but other cereal crops are above normal and with wise economy we should have no difficulty in supplying both our needs and the requirements of our Allies. He said that in spite of all the pleadings with the people of the country the consumption of sugar during the last four months has not decreased and the consumption of fat has increased since the opening of the war by 10 per cent. According to the calculations made, the average consumption of fat *per capita per diem* in this country is 150 grams. Mr. Hoover said that during his two years' experience in Belgium the ration allowed contained 40 grams of fat, 60 grams of protein, and 300 grams of carbohydrates. The 40 grams of fat were entirely sufficient for the population except for adolescent children. For them the ration was increased by special lunches in the schools, consisting chiefly of fatty foods. He made a plea for help on the part of the health agencies of the country, which can be best accomplished by the education of the people to the importance of moderate eating and to the multifarious ailments which follow over-indulgence. He also stated that in 70 per cent. of the homes of this country no food is being wasted, and that in 30 per cent. of the households so much is being wasted that if these households would save the unnecessary waste two-thirds of the national problem would be met.

Pellagra.—An interesting side-light on the relation of food and disease was presented by Dr. LOUIS I. DUBLIN in his paper on pellagra. The conclusions of the paper were based on the study of 2000 deaths which occurred among the policyholders of the Metropolitan Life Insurance Company in the southern states. The records were studied with a great deal of care and covered the period from 1911 to 1916. The year 1915 was a very heavy year for pellagra which exacted more deaths in the region than scarlet fever. The reason for this high mortality was ascribed to the bad financial conditions of 1914 following the opening of the war, with its disastrous effects on the cotton growers of the South. In 1916 the pellagra death rate uniformly dropped over 50 per cent. It went down to the rate of 1911 in every district. In the discussion it was pointed out that next year, following the present food shortage, may again show an increase in the incidence of pellagra. It may also be of interest to note that on the basis of the study, the death rate from pellagra was found to be much higher for the negroes than for the white race, it was higher for females than for males, and it was higher for adults than for children. It is very rare as a cause of deaths in infants and children. At the age of fifteen years it begins to appear and goes up rapidly with advancing years.

Poliomyelitis Serum.—Dr. E. C. ROSENOW of Rochester, Minn., presented a short report on the effects of the horse serum treatment of poliomyelitis as established in the experiments at Davenport, Iowa. As his report has already been published (see MEDICAL RECORD, Oct. 13, 1917, page 649), it is not necessary to go over it in detail again. Excluding 7 moribund cases from a group of 56 patients treated, he had a fatality of only 5.3 per cent. and in all other cases the treatment has been carried out with strikingly good effects. His results are probably the best thus far reported. He has on hand serum sufficient to treat a considerable number of patients and it can be obtained from him free of charge for trial in localities afflicted with an epidemic of poliomyelitis.

Hospital Statistics.—The medical and social value of uniform hospital statistics was discussed in the report of a special committee headed by Dr. F. L. HOFFMAN of the Prudential Life Insurance Company's Statistical Department. The report advocates a simple but uniform classification of patients by principal groups of disease, sex of patients, length of stay in hospital with subdivisions of condition on discharge. The plan advocated is along the lines of the splendid report recently published by Johns Hopkins Hospital. Comparability of hospital statistics is necessarily predicated on uniformity of classification of diseases, but the report does not definitely suggest what this classification should be. "Whenever classification is ultimately adopted it should, as far as practicable, be in conformity to the classifications of industrial accidents by causes or contributory circumstances in use in workmen's compensation or industrial accident boards." The report pointed out that our hospital statistics are in the most neglected branch of medicine and their application to vital questions such as health insurance and others belongs to the future rather than the present or the past. We have been and are spending great amounts of money for the publication of unscientific hospital reports without any reference to other reports and without any particular value. In England the hospitals make reports to the Metropolitan Asylums Board of London or to the Medical Officer of the Local Government Board and the amount of available data from the collective investigation of hospital experience is of great medical and social value. The committee which drew up the report is of the opinion that it would be advisable to arouse public interest in the possibilities of a collective hospital statistics compilation under the immediate direction of the United States Public Health Service. It would not involve, in the opinion of the committee, very material expense on the part of the large hospitals to send a weekly report to the office of the Surgeon General of the United States Public Health Service for tabulation and analysis. At the beginning the reports would be limited to a small number of important items and gradually could be enlarged as occasion demanded.

Dr. CHARLES SCOTT MILLER gave an account of the attempt made in Philadelphia to bring about the uniform registration of hospital statistics for the aid it affords in public health administration. The plan seems to be working out very well but the time it has been in operation is not long enough to warrant definite conclusions.

In the City of New York the need of hospital statistics was first emphasized by Dr. Charles F. Bolduan of the New York City Health Department, in which the form of a tabulation chart was worked out. The Metropolitan Life Insurance Company has recently authorized its statistical department to undertake the tabulation of statistics of several of the larger representative hospitals along the lines suggested, but because of some minor difficulties the report and collection of the statistics has not yet been begun.

In this connection the adoption by the Public Health Association of the report of the Committees on the Revision of the International List of the Causes of Death may be mentioned. This painstaking report, the preparation of which took two years' time and a great deal of energy and effort, will be of great service to all the registrars of vital statistics all over the country. It presents to them a summary of our present knowledge of pathology and indicates which causes of death may be accepted without supplementary evidence, such as laboratory tests or autopsy findings. It is one of the most useful aids in improving our vital statistics and will prove to be of inestimable value to all statistical workers. The idea of the plan was conceived by Dr. Haven Emerson, present Health Commissioner of New York City, who was aided in the endeavor especially by William R. Williams, M.D.; Warfield T. Longcope, M.D.; Charles Norris, M.D., and Mr. George H. Van Buren of the Statistical Department of the Metropolitan Life Insurance Company.

Public Health Education.—This constituted one of the topics of lively discussion. Dr. JOHN W. TRASK, Assistant Surgeon General of the United States Public Health Service, gave an able survey of the chief avenues of public health education. In his estimation the day is not far distant when in the newspapers the health column will be as indispensable as the joke column. He urged that the family magazines and educational periodicals increase their usefulness by maintaining well edited departments for the discussion of matters relating to personal and community hygiene and pleaded that the public be made to realize that instruction in the principles of hygiene and how to live successfully is as important as instruction in the three R's.

Dr. Ira S. Wile of New York gave an outline of a plan for health education of school children, suggesting that health education be established in all grades and be taught all the time. He believes that much of the material now prepared for health education among adults is wasted. This view, however, was disputed for according to one speaker the commercial auvertisers certainly knew what they were doing and were undoubtedly getting results.

Dr. W. S. Rankin of Raleigh, North Carolina, pleaded for some sort of a gauge of the usefulness of certain media of education, such as moving pictures for example. His claim was that people going to moving pictures go to be entertained and not to be instructed, and he ended by saying: "How many of you remember two days after seeing a screen play the plot or even the name of the play?"

Dr. Charles F. Bolduan of New York was of the opinion that moving pictures are a great help in educational work and he considered the movies as one of the best avenues of bringing to the people the message of health. In his judgment effort should be made to induce the moving picture theatres to include a health real in every regular program.

Industrial Hygiene.—The conservation of the health of workers, which has been a matter of discussion and consideration for many years, has assumed acute importance in the present crisis when additional strain is being put upon industrial classes. Mr. D. D. Kimball of New York emphasized the need of revision of our ventilation standards in conformity with the recent researches made by the New York Ventilation Commission and other modern studies based on physical rather than quantitative standards. Correct temperature, prevention of excess of humidity and air movement are the essential features of good ventilation. He gave an outline of the contributions to this subject in the past year.

Starting from the same premise of the paramount importance of conserving energy and health, Prof. Frederic S. Lee of New York read a paper on the "Bearings of Physiological Science on Industrial Efficiency." One of the greatest problems of the day is the solution of the problem of "how the human machine can be used so as to obtain from it the greatest advantages." To this problem the Health of Munition Workers Committee in Great Britain and our own Committee on Industrial Fatigue of the Advisory Commission of the Council of National Defense have dedicated their energies and efforts. A large number of studies have been made, and they all point to the fact that the old view of employers of labor that long hours necessarily mean a greater output is absolutely erroneous and saps the energy of the nation's workers. All the physiologic evidence points to the need of introducing recess periods into long spells of labor, to omitting Sunday work, and against the imposition of overtime on already fatigued workers except in rare emergencies and only when compensation can be given by free hours later. He advised against keeping the same workers continually on night shift, and pointed out that each worker has a rhythm which is best adopted to his neuromuscular mechanism, and that it is advantageous to place in a squad of workers doing a specific task only those possessing similar rhythm.

The special sub-committees appointed by the President of the American Medical Association at the request of the Labor Section of the Council of National Defense made their reports at the meeting. They were charged with the task of formulating standards for industrial establishments which shall be accurate and simple. Various ingenious apparatus have been devised for measuring and testing conditions. Mr. L. B. Marks of New York has been able to obtain accurate results in testing lighting with a small photoscope which requires only a simple adjustment to record candlepower of any intensity. Dr. Hills of Chicago has devised an apparatus for counting dust particles in the air by means of which a measured quantity of air is forced over a half-inch plate with a sticky surface and the particles counted under the microscope. To guard against errors he has arranged a sequence of nozzles similarly loaded with adhesive glass plates so that the dust particles, if not caught on the first, will become attached to the second, third, or fourth plate. The intensity of odors can also be measured by a special instrument. Probably the most valuable contribution made was a chart for plotting the condition of the atmosphere as to temperature, moisture, motion, odor, dust, bacteria, and chemical composition. This chart is graded between a zero point at which life would be impossible and a 100 per cent. ideal condition. Dr. Hills did not claim for this chart perfection, but thought it would be valuable as a basis for measuring and comparing existing conditions and of basing on them the necessary improvements.

Dr. George M. Price offered a report on shop and industrial sanitation. Representatives of industrial plants met with the scientific workers and discussed various standards of industrial sanitation. There was an active debate regarding the frequency of medical examination of persons employed in hazardous processes, and a great deal of difference of opinion developed on this point, some favoring examination every 30 days. No final conclusions have as yet been reached concerning the various topics involved.

That the adoption of such standards at the earliest time is necessary was strikingly brought out by Dr. Emery R. Hayhurst of Ohio. He pointed to the fact of the increasing number of industrial accidents and diseases, and also to the special need of protection because of the large number of women and juveniles that are being taken into industry to make up for the shortage of man power.

Scarlet Fever.—A statistical study of scarlet fever was presented by Frederic S. Crum, Assistant Statistician of the Prudential Life Insurance Company. The study is based on data drawn from various countries, and the most important conclusions which can be derived from it are as follows: Scarlet fever has been decreasing in prevalence and fatality in recent years everywhere. It seems to be gradually disappearing under the concerted and intelligent efforts of modern medicine and sanitation. It is less prevalent in tropical and semi-tropical climates than in temperate zones, and the negro race seems to be less susceptible to its ravages than the white race. Mortality from scarlet fever is higher in urban than in rural areas. The world-wide decline in scarlet fever, as noted above, has effected the United States also, and during the period from 1900 to 1915 there was a considerable decline, but the urban still averages twice the rate of the rural areas. It is 10 in the urban centers and 5.8 in the rural areas per 100,000 of population. Both sexes appear to be almost equally susceptible to the attacks of scarlet fever in the United States. At the ages under five years of life the mortality among males is slightly higher than the mortality among females; but in England and Wales sex differences are most negligible. In this respect scarlet fever differs from the other three communicable diseases of childhood. It is most frequently fatal in the third year of life; it is also comparatively dangerous in the second and fourth years of life. Up to the third year it is less important as a mortality factor. At no age does it approach diphtheria. During and subsequent to the fourth year of life it is a more important mortality factor than either measles or pertussis. Scarlet fever is very frequently accompanied by secondary complications which either run a fatal course or result in serious permanent disabilities. The experience of the Prudential Life Insurance Company for the years 1914-1916, embracing 1485 deaths, shows that the largest number of complications (130) were with acute Bright's disease; next was chronic Bright's disease, 93; next in numerical importance was pneumonia, 59 cases; acute endocarditis in 56 cases; bronchopneumonia in 54 cases; diphtheria in 39 cases; and meningitis in 39 cases. The statistics of the Metropolitan Asylums Board of London during 1910-1914 show that out of a total of 63,085 cases of scarlet fever 27,190, or 43.1 per cent., were accompanied by complications. Otitis was present in 5981 cases, albuminuria in 4711 cases, adenitis in 3835 cases, nephritis in 1889 cases, rheumatism in 1855 cases, chicken pox in 1117 cases, diphtheria in 1041 cases and tonsilitis in 1012 cases.

Puerperal Diseases.—A report on the deaths from puerperal causes in the State of New York outside of New York City was given by Dr. William J. V. Deacon. The study made covers a 10-year period from 1907 to

1916. The average death rate from puerperal causes in New York State has been lower than for the entire registration area; in 1916 it was 12.2 per 100,000 population, while the registration area rate was 14.9 in 1915. Despite the fact that the New York rate is lower than that of the registration area, it is much higher than that of foreign countries, Sweden, for example, showing a death rate of 6.0, Norway 8.1, Italy 8.9, France 10.3, Prussia 10.4 and England 11.1. Of all the puerperal diseases, puerperal septicemia claimed the largest percentage of victims, 38.1 per cent. of all the deaths from puerperal diseases being due to this cause; the second was puerperal albuminuria, which claimed 27.4 per cent. of all the fatalities. It is almost inexplicable why the death rate from puerperal conditions should be so much higher in this country than abroad, particularly when we consider that a large percentage of foreign-born women are included in our population. It is estimated that 41 per cent. of the women included in the study were of foreign birth and 59 per cent. were native born. Surprising was the statement in Dr. Deacon's paper that the mortality from puerperal causes is larger in urban communities than in rural, which seems contrary to all the usual statements and assumptions. In 1916 the figures showed that the percentage of deaths from all puerperal causes was 59.1 in cities and 40.9 in country districts. From puerperal septicemia alone there were 66 per cent. of all the deaths from puerperal causes in cities and 44 per cent. in country districts. The reasons for this condition are far from being well understood, and it would seem that a careful study of the problem, either on the part of private health agencies or the public, is strongly indicated.

The Importance of Public Health Laboratories.—In a series of papers the importance of laboratories was emphasized. Prof. HENRY ALBERT of Iowa presented a summary of the services of the several State public health laboratories with reference to wartime activities. The summary is based on a questionnaire which he sent to all the State laboratories, and indicates the extent to which the laboratories are being utilized for military purposes, and of what extension they are capable in the future. Some laboratories reported that they are handicapped by the drafting of their trained workers, and a plea was made for the exemption of men in laboratory work because of the need of their services to the military establishment, as well as for the welfare of the civilian population.

Dr. WILLIAM H. PARK of New York presented a most instructive report on immunization against typhoid fever and on the spread and prevention of cerebrospinal meningitis in the English and French armies. The troops have suffered several outbreaks of this latter disease. The rôle of carriers in the spread of epidemics of meningitis was discussed at length, as was also the effect of vaccines in checking its spread.

Both Dr. Park and Major Edouard Rist of the French Army discussed the effects of immunization against typhoid and paratyphoid fever, and showed how, by the gradual introduction of the vaccine, the two diseases have been practically eliminated from the army. At first a large percentage of the troops had not been vaccinated against either typhoid or paratyphoid. Gradually the typhoid vaccine has been extended, and, while there has been a decrease in the incidence of typhoid, the prevalence of paratyphoid remained unchecked. The paramount importance of a triple vaccination has been fully demonstrated.

Resolutions.—The sessions of the conference ended on the afternoon of Saturday, Oct. 20, 1917, and a number of resolutions were adopted, among which were the following:

Resolved, That the American Public Health Association urges upon all Federal, State and local health authorities; upon physicians, hygienists, and sanitarians; and upon all organizations interested in or dealing with the public health, the importance of unusual solicitude and activity in conserving and promoting the health of the citizen population during and after the present war.

Resolved, That the Council of National Defense be requested to have established immediately under the U. S. Public Health Service a bureau of information that shall promote the installation of medical supervision in all plants employing 1000 or more employees; and that all industries engaged in governmental work be required to institute such medical supervision.

Resolved, That the thanks of the American Public Health Association be extended to the American Red Cross for its establishment of a bureau of sanitary service for the purpose of assisting the various health authorities in the maintenance of effective sanitary control of the communities adjacent to cantonments and other important military establishments, and that the American Public Health Association pledges itself to cooperate fully and heartily, whenever desired, with said bureau, and all other activities of the Red Cross, for the conservation and promotion of the public health.

Whereas, Mr. Herbert C. Hoover, Federal Food Administrator, in addressing the American Public Health Association on Oct. 19, 1917, stated that the food conservation problem was largely and primarily an educational problem; and

Whereas, Mr. Hoover, in the same address, made the practical suggestion to the health officers assembled that they could be of most service in his work by directing public attention to the hygienic aspects of food conservation; and

Whereas, Public health agencies, State and municipal boards of health, are well equipped with educational means, such as bulletins, special educational pamphlets, press service, and exhibits for reaching the public; and

Whereas, Most public health agencies do not have in their personnel persons who can prepare suitable educational material for the aforementioned means of publicity; and

Whereas, Such deficiencies in the personnel of the various State and municipal boards of health would be supplied and the ends of efficiency and economy met by some provision in the office of the Federal Food Administrator for furnishing suitable bulletins and press material to public health agencies; therefore, be it

Resolved, That the American Public Health Association appoint a committee of three to respectfully suggest to the Federal Food Administrator the creation of such agency as suggested in the preamble; and be it further

Resolved, That this Association pledges to the Federal Food Administrator its sympathetic and full support, and its earnest cooperation in aligning of public health agencies, whether or not they be affiliated with this body, in carrying into effect the plan herein suggested.

Dr. CHARLES J. HASTINGS of Toronto, Canada, was elected President.

E. H. L.-C.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, Held October 4, 1917.

THE PRESIDENT, DR. WALTER B. JAMES, IN THE CHAIR.

Principles of the Treatment of Wounds. — Dr. ALEXIS CARREL delivered this address. He stated that the principles for the treatment of wounds which he would describe had been developed in the course of two years by a group of men with which he had had the privilege of being associated. The methods found were of such kind that it required the team work of men trained along different lines. This group was composed of five surgeons or medical men, Drs. Dehelly, Guillot, Woimant, Dumas and Audigane; of a mathematician and physicist, Captain Lecomte du Nouy; of two chemists, Dr. Dakin and Dr. Daufresne, and of a bacteriologist, Dr. Vincent. The purpose of the method was to prevent or to stop suppuration, to sterilize the wound and close it. These results they had succeeded in obtaining, but the method involved no new principles. It was derived directly from Pasteur and Lister. No new surgical procedures were invented. The techniques they used are known to every surgeon. Neither was the method characterized by the use of any new chemical substance, the antiseptic power of hypochlorite of sodium having long been recognized. The results had been obtained by systematizing these old procedures in a new way. This new systematization had been brought about by the application of two quantitative methods. Accurate measurements are the neeessary condition of

scientific progress. The use of the scale caused the wonderful growth of chemistry. Medicine was so slow because of the failure to use quantitative methods. The two methods which they had employed were simple ones. The first was that of measuring the volume of infection and of following its increase or decrease; the second was that of measuring the progress of healing by means of a technique based on the discovery of some of the laws of cicatrization. Thus the volume of infection and the rate of healing were accurately measured and it became possible to handle the infection without interfering with the cicatrization. It was only after thousands of observations and clinical experiments that the method was considered as established. This method might be defined as a combination of procedures consisting of four parts: (1) Mechanical sterilization. (2) Chemical sterilization. (3) Bacteriological control. (4) Closure of the wound. None of these parts could be separated from the others; all were essential to the successful treatment of wounds by this method.

1. One could not sterilize a wound properly by chemical methods unless it was first sterilized mechanically, and one could not close the wound until it was shown by the bacteriological control to be aseptic. The problem of mechanical sterilization of a fresh wound was a very simple one as they had worked it out in their hospital at Compiègne, especially by Dr. Dehelly. The surgical cleansing of a wound must be made not at the first aid dressing station, but at the casualty clearing station. The casualty stations are usually situated from five to seven miles from the front lines, and when the patients were brought to these stations the mechanical cleansing could be effected by large incisions opening to the deepest parts of the wound. After the wound was laid open and explored for shell fragments, pieces of clothing, or other foreign bodies, every particle of foreign matter was removed. This was easy to do if one received the patient a few hours after he had been wounded. The bacteria were usually carried by particles of clothing or other foreign bodies and were easily removed from the surface of the tissues by the mechanical sterilization of the fresh wound. Dr. Carrel emphasized very strongly the necessity of thoroughness in the removal of all foreign bodies, since it was from these that gas bacillus infection usually started, and pieces of clothing were likely to carry the spores of the Welch bacilli. Blood clots must also be carefully removed and hemostasis made, because bacteria were located in the blood clots and the hypochlorite could not rapidly dissolve the blood clots. If the patient was received a few hours after being wounded, in many instances the wound could be mechanically cleansed and closed. But immediate closing of a wound was not a scientific method. One was justified in using this method only when he was absolutely sure that the patient could not be evacuated for ten days; otherwise a primitive suture should never be made. The treatment of old suppurating wounds was different. In many instances of suppurating surface wounds this mechanical cleansing and washing with neutral sodium oleate and water brought about a surprising degree of sterilization, though it might not last long. When one was dealing with old suppurating wounds with fractures, the problem was very much more complicated. In this class of cases a surgical operation should not be attempted until at least ten days after the infection was decreased by chemical sterilization. Only such surgery as was absolutely imperative should be made at this stage of infection. The suppurating wound was treated by chemical means, and when the infection was reduced as much as possible, the necessary surgical cleansing was performed. It was then completed by a new and thorough chemical treatment.

2. The chemical sterilization in itself was a comparatively simple procedure and could be defined as a combination of processes by which chemical substances were used under specific conditions of contact, concentration, and time, for the purpose of securing surgical asepsis. The antiseptic substance was an instrument. It played the same role as a scalpel in a surgical operation. One should be selected which best fitted the purpose for which it was to be used. Surgeons used different kinds of antiseptics just as they used different kinds of surgical instruments. We must have an antiseptic which killed the bacteria but did not destroy the tissues. In order to know the practical value of an antiseptic, we must have a measure of its action on the bacteria and on the tissues. This was made by measuring the volume of infection and by the proper use of the algebraic formula of Captain du Nouy. Among the excellent substances studied by Dr. Dakin at the beginning of the war, Dr. Carrel selected two, sodium hypochlorite and chloramine-T. He gave the name of Dakin's solution to sodium hypochlorite, deprived of its alkalinity, in order to distinguish it from Lebarraque's solution which contained a great deal of alkali. Chloramine-T, which was soluble in water and had a high antiseptic power, differed from sodium hypochlorite in that it did not dissolve necrotic tissues and was less irritating, and might be used on skins which were more than ordinarily sensitive. Almost the same results might be obtained with magnesium hypochlorite, but it was less satisfactory than sodium hypochlorite because the magnesium dissolved very little of the necrotic tissue. Flavine and dichloramine-T dissolved in oil and several other substances had been experimented with and found far inferior to hypochlorite and chloramine-T. Comparison of the curves of sterilization and of cicatrization showed that the neutral hypochlorite of soda in 0.45 per cent. solution, used twelve times in twenty-four hours, sterilized a wound without producing any destruction of the tissues. Extensive experimental work was made by Daufresne in the properties of sodium hypochlorite. The action of hypochlorite on bacteria was rapid. Most of the microorganisms were destroyed in one or two minutes by sodium hypochlorite and in five or ten minutes the hypochlorite was then destroyed by the tissues. Sodium hypochlorite destroyed plasma, clots, necrotic tissues, and blood clots, while chloramine-T and dichloramine-T in oil did not. The methods of making hypochlorite had been very much simplified. Daufresne found that potassium permanganate stabilized hypochlorite. Then electrolytic hypochlorite could be used. Afterwards in this country it was found that a very simple method of preparation was to bubble liquid chlorine through sodium carbonate. Daufresne mixed in a certain way Dakin's chloramine-T with sodium stearate and obtained a paste which gave up slowly the antiseptic substance and was very much more severe than dichloramine-T in oil.

It should be remembered that the efficiency of an antiseptic was due chiefly to the way in which it was used. In the treatment of wounds the three important conditions in connection with its use were contact, concentration, and time. Contact was highly important. It was plain that the solution could sterilize only the tissues with which it came into contact, and that was why the surgical and mechanical cleansing were so important. The mechanical cleansing had to be so thoroughly done that every part of the wound could be reached by the chemical substance. Then small rubber tubes with a number of perforations were used to carry the solution to every part of the wound. The second condition was concentration. When the antiseptic solution came into contact with the surface of the wound it was destroyed, and it was diluted by the secretions from the wound, with the result that in a very short time, fifteen or twenty minutes, no active substance remained. Proper concentration could be kept up only by bringing the antiseptic constantly to the wound. It was found that a wound flushed every two hours became sterile. In mildly infected wounds the Daufresne paste kept at the surface of the wound a sufficient concentration of chloramine-T. When this paste was applied to the surface of a wound the sodium stearate disappeared and chloramine was brought to the tissues. But this technique was successful only when the amount of suppuration was small. It would be useless to attempt to sterilize an abundantly suppurating fracture with a small amount of chloramine-T such as could be contained in the cavity of the wound. Antiseptic flushing should be used. The third condition to be considered was that of time. It was not possible to sterilize a wound in a few hours. A surface wound might be sterilized in twenty-four hours, but generally in war wounds it took a longer time. The treatment could be stopped only when the bacteria had disappeared or almost disappeared from the smears taken from the wound, and then the wound could be safely closed.

3. The third factor in the treatment was the bacteriological control. Without knowing the degree of infection and without following the progressive decrease in the number of bacteria it would be impossible to know whether the technique was carried out in the proper way or when the wound should be closed. When a large number of wounds had to be watched it was found impossible to use the ordinary bacteriological methods. The only way that seemed practical was to take smears and count the bacteria on the surface of the smear. This method was inaccurate but had been found to be very good from a practical standpoint. The smears were taken every two days from the back parts of the wound and the recesses in which infection would be most likely to lurk. It was important to know, not the average bacterial count, but the condition of the more badly infected part of the wounds, because it does not matter if nine-tenths of a wound be sterile if one-tenth remained still infected. The work of counting the bacteria could be done by mere technicians. It was possible to examine thirty or forty slides per hour, and as the examinations were made every other day a large number of wounds could be examined bacteriologically. The bacteriological chart of every wound was plotted and gave to the surgeon the necessary information about the condition of each wound. It told when the antiseptic was properly applied and when the wound could be closed. When the time was reached that only one bacterium was found in five or ten fields, the wound was said to be surgically sterile and might be stitched with safety. Some bacteriological charts were as characteristic as were the temperature charts in typhoid fever. In suppurating surface wounds where there was no necrotic tissue there would be a sudden drop in the number of bacteria, from a large number to one in five or one in ten fields, after twenty-four to forty-eight hours, but where there was necrotic tissue the count would remain high for two or three days. In cases of deep wounds the drop in the bacterial count was generally slower. The curve was especially characteristic in cases of suppurating fractures, if the wound contained some foreign body. The count would be very high and would then drop to about ten per field. If one operated on these cases and removed the foreign body the count would go up to 100 or more, and after two or three days would drop to one per five or ten fields. After a few weeks' experience one might diagnose the case at first sight of the curve, determine the character of the complication, and tell the process to be followed in the treatment. When the bacteria had disappeared it did not mean that the wound was bacteriologically aseptic. Dr. Vincent found that only about thirty per cent. of the surgically aseptic wounds were bacteriologically aseptic. But when the count had dropped to one in five or ten fields, the wounds could be closed. When one was dealing with a surface wound or a wound of the soft parts the wound could frequently be closed after two days of asepsis; but in cases of fracture, one had to be very careful and study the clinical symptoms as well as the bacteriological curves. When both clinical symptoms and bacteriological chart agreed, a fracture, say of the thigh, might be closed after five or six days after the wound was found surgically aseptic.

4. For the closing of the wound, which was the fourth step in the method, there was no special procedure to be used. The wounds were closed by strapping with adhesive plaster in the cases in which the wounds were sterilized in less than ten days. When there was a loss of skin the elastic traction method was used. In most of the cases the wounds were stitched. No drainage was made. When the patients were brought with already suppurating wounds, especially with fractures, the closing had to be done by following the rules studied especially by Dr. Guillot and Dr. Woimant in Compiègne. About sixty per cent. of the old suppurating fractures of the thigh could be sterilized and closed.

Dr. Carrel said he could best illustrate the results of the application of the principles which he had described by means of lantern slides. He then showed characteristic bacteriological curves, and demonstrated the manner in which the curve of cicatrization should follow the calculated curve in a properly treated wound, the manner of arranging the perforated tubes and the dressings, emphasizing the point that the dressing should be loosely packed about the tubes and that in changing dressings one should never touch the granulating surfaces. He showed the results obtained in fractures and stated that a great many suppurating fractures could be sterilized and closed thus avoiding amputation in many instances and saving much suffering. Their conclusion after three years' experience was that suppuration could be suppressed and that no patient should be allowed to suppurate for more than three or four days after his coming to the hospital. Septicemia could almost always be prevented and a great many limbs could be saved. At least fifty per cent. of the amputations performed for infection could have been avoided if sterilization of the wounds had been effected. The time required for treatment was greatly reduced. As an average it was only thirty-three per cent. of the ordinary time. It should be remembered that a precise method required more care than the old methods. But more systematized work in the hospitals, by the surgeons and their assistants would most certainly yield an immense improvement in results.

Dr. ABRAHAM JACOBI made a few remarks in which he expressed the gratitude and the sense of obligation which he said all must feel toward Dr. Carrel for having come there to teach them. This was not the first time the French had come to our aid, since the time of Lafayette they had helped us, not only by fighting for us but by teaching us. We had learned much from France as well as from other countries. He therefore moved that the New York Academy of Medicine express its sense of obligation to Dr. Carrel for what he had done in France and for the teaching he had brought to them this evening.

A unanimous vote of thanks was given to Dr. Carrel.

Essential Giant Cells in the Hypophysis.—Simmons has found among 2,000 cases of histologically studied hypophyses 4 cases of giant cell formations in which tubercle, syphilis, and foreign bodies could be excluded as causes.—*Virchow's Archiv.*

Morphinomania and Nephritis.—According to Pron and Guelpa a healthy man began to waste away without apparent cause and was found to have albuminuria which failed to respond to the milk regimen, although no evidences of nephritis were then obtained. At this juncture patient began to receive morphine for sphincteralgia. A diagnosis was eventually made of syphilitic albuminuria and nephritis, refractory to specific treatment. The return of the anal fissure led to the morphine habit. Despite these vicious circles the patient actually recovered his health completely after some years—during which he must have had minor uremic crises—save for the persistence of albuminuria.—*Journal de médecine de Paris.*

Trees and Lightning.—In various parts of the world and in various ages certain kinds of trees have been popularly believed to be immune to lightning and such have been sought for shelter in thunder storms. In Ancient Rome these trees comprised the laurel, mulberry, peach, boxwood, etc. Today in Europe this series is represented by the beech (also in America), birch, linden, and resinous trees. Statistics have shown that over half of the lightning strokes have occurred under poplar trees. The beech stands low in the scale, but the elm, pine, and oak do not show a high per cent. of victims. The analysis will show that other factors aside from mere species determine the relative frequency, as shape and height of trees, isolated position, etc.—*Bulletin générale de thèrapeutique.*

Adrenalin Content of the Adrenals in Various Fatal Diseases.—Lucksch has examined 350 cadavers by the Jolin method to determine this content. In the newly born the latter is very low and still lower proportionally to mass in yearlings. There is a general increase from 1 to 10 years, while from 10 to 90 years the values are nearly constant, with a maximum at 50. The average autopsy weight of the adrenals in hospital material is 4.3 mgm. On the other hand the average weight for individuals suddenly deceased in the prime of life and health is nearly twofold the preceding—7.25 mgm. Values are low in anomalies of constitution and infectious diseases, and after burns. In organic diseases and in tumors a depression of values is not marked—in fact the content is extremely high in nephritis.—*Correspondenz-Blatt für Schweizer Aerzte.*

Books Received.

The MEDICAL RECORD *is pleased to receive all new publications which may be sent to it, and an acknowledgment will promptly be made of their receipt under this heading, but it must be with the distinct understanding that it is under no obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.*

MEDICAL BACTERIOLOGY. By JOHN A. RODDY, M.D. 285 pages, illustrated. Published by P. Blakiston's Son & Co., Philadelphia. Price, $2.50.

THE DESTINY OF THE AMERICAN SURGICAL ASSOCIATION. By J. EWING MEARS, M.D. 12 pages. Reprinted from the Transactions of the Association, Vol. XXXV, 1917. Published by William J. Dorman, Philadelphia.

A TREATISE ON REGIONAL SURGERY. By various authors. Edited by JOHN FAIRBAIRN BINNIE, A.M., C.M., F.A.C.S. Vol. II, 656 pages, illustrated. Published by P. Blakiston's Son & Co. Price, $7.00, net.

A MUNICIPAL SANITARY CRISIS. An account by various writers of an epidemic of infantile paralysis in New Rochelle, N. Y., in 1916. Compiled by A. W. HOYT, M.D., President of Board of Health.

ANAPHYLAXIE, ANTIANAPHYLAXIE. By A. BESREDKA. Preface by E. ROUX. 146 pages, illustrated. By Masson & Cie., Editeurs, Paris. Price, 4 francs.

THE MEDICAL CLINICS OF NORTH AMERICA, Vol. 1, No. 2. 464 pages, illustrated. Published bi-monthly by W. B. Saunders Company, Philadelphia and London. Price per year, $10.00

INTERNATIONAL CLINICS. A quarterly of illustrated clinical lectures and especially prepared original articles. Edited by H. R. M. LANDIS, M.D., Philadelphia, with the collaboration of CHARLES H. MAYO, M. D. Vol. 3. Published by J. B. Lippincott Company. Price, $2.00.

MASSAGE, ITS PRINCIPLES AND PRACTICE. By JAMES B. MENNELL. 358 pages, illustrated. Published by P. Blakiston's Son & Co., 1012 Walnut Street, Philadelphia, Pa. Price, $3.00.

OBSTETRICS, NORMAL AND OPERATIVE. By GEORGE PEASLEE SHEARS. 745 pages, illustrated. Published by J. B. Lippincott Company, Philadelphia and London. Price, $6.00.

THE SURGICAL CLINICS OF CHICAGO, Vol. 1, No. 4. 887 pages, with 71 illustrations. Published bi-monthly by W. B. Saunders Co., Philadelphia and London. Price, $10.00 per year.

HUMAN PHYSIOLOGY. By PROF. LUIGI LUCIANI. Translated by FRANCES A. WELBY. In five volumes. Vol. 4, 519 pages. Published by The Macmillan Co., New York. Price, $5.25.

THE CAUSATION OF SEX IN MAN. By E. RUMLEY DAWSON. 226 pages, illustrated. Published by Paul B. Hoeber, New York. Price, $3.00.

ANNUAL REPORT OF THE SURGEON GENERAL OF THE PUBLIC HEALTH SERVICE OF THE UNITED STATES FOR THE FISCAL YEAR 1916. Published by the Government Printing Office, Washington.

RADIUM THERAPY IN CANCER AT THE MEMORIAL HOSPITAL. By HENRY H. JANEWAY. 242 pages, illustrated. Published by Paul B. Hoeber, New York. Price, $2.25.

RECOLLECTIONS OF A NEW YORK SURGEON. By ARPAD G. GERSTER. 347 pages, illustrated. Published by Paul B. Hoeber, New York. Price, $3.50.

SURGICAL CONTRIBUTIONS. By RUTHERFORD MORISON. Vol. 1, General Surgery. 427 pages, illustrated. Vol. 2, Abdominal Surgery. 953 pages, illustrated. Published by William Wood & Co., New York. Price, $10 per set.

ST. LUKE'S HOSPITAL MEDICAL AND SURGICAL REPORTS. Vol. 4. 403 pages, illustrated. Published by The Press Publishing Co., East Stroudsburg, Pa., 1917.

AN INTRODUCTION TO THEORETICAL AND APPLIED COLLOID CHEMISTRY. By Dr. WOLFGANG OSTWALD. First Edition. 232 pages, illustrated. Published by John Wiley & Sons, Inc., New York; Chapman & Hall, Ltd., London. Price, $2.50.

REFERENCE HANDBOOK OF THE MEDICAL SCIENCES. Vol. 8. By Various Writers. Edited by THOMAS L. STEDMAN, M.D. 782 pages, illustrated. Published by William Wood & Co., New York. Price, $8.00; sold only by subscription.

Therapeutic Hints.

Tinnitus Aurium.—

℞ Tinct. cimicifugæ.....3iij.
Aquæ .....3ij.
M. Sig.: Teaspoonful three times a day.

Pyrosis.—

℞ Quin. sulphatis.....gr. xij.
Ac. sulphurici dil.....
Spts. chloroformi.....āā 3ij.
Tr. aurantii cort.....q.s. ad. 3ij.
M. Sig.: Teaspoonful in water three times a day.

℞ Tr. nucis vomicæ.....3iij.
Acidi nitrici dil.....3v.
Syr. zingiberis.....q.s. ad. 3iij.
M. Sig.: Teaspoonful in water three times a day.

Nausea of Pregnancy.—

℞ Tr. cantharidis.....
Tr. ferri chloridi.....āā 3j.
Aquæ .....3ij.
M. Sig.: Teaspoonful in water three times a day.

Relief of Chronic Laryngitis.—Boulai has employed the following for the treatment of laryngitis of the chronic type:

℞ Tincture of eucalyptus.....50 g.
Tincture of benzoin.....25 g.
Tincture of iodine.....1 to 2 g.
Menthol .....2 g.
Beech tar.....5 g.

One teaspoonful is added to boiling water in an inhaler and inhaled.—*Jour. de Med. et de Chir. prat.*, July 10, 1917.

Antiseptic Gargle and Mouth-Wash.—The following may be used to check fetidity of the mouth, caused by the presence of decayed teeth:

℞ Thymol .....0.50 g.
Borax .....1.0 g.
Alcohol .....2.0 g.
Distilled water.....1 litre.

A few drops are added to a glass of water and the mouth and throat thoroughly rinsed.—*Jour. de Med. et de Chir. prat.*, July 10, 1917.

Hydrotherapy for Pruritus.—From a Dutch medical journal comes a report of the cure of a severe case of essential pruritus by the use of cold water. The patient was instructed to sponge his whole body with cold water every morning on rising, then to return to bed without drying himself and to remain there until thoroughly warm. A week effected the cure. The explanation offered of the result obtained was that the vasoconstriction from the cold water, followed by the dilatation from the warmth in bed, modified the vasomotor nerves and possibly aided in the expulsion of irritating substances in the sweat glands.—*The American Journal of Nursing.*

Cathartics Contraindicated After Childbirth.—Cathartics were not given to 322 patients after childbirth. If no movement occurred within three days a saline enema was given, which was again given in three days if there had been no natural stool. Of the number thus treated but three had fever, one of these having a mammary abscess. No coated tongues, no foul breaths or headaches, nor breast complications followed. This treatment discourages routine drugging.—*Bulletin of the New York Lying-in Hospital.*

BREAST FEEDING.

BY MARK S. REUBEN, M.D.,

NEW YORK.

ASSISTANT IN DISEASES OF CHILDREN, COLUMBIA UNIVERSITY; IN CHARGE OF THE INFANT FEEDING STATION.

IN medicine, as in every other field, action and reaction are equal and contrary. While the campaign for the encouragement of breast feeding and for the conservation of human milk, has accomplished much good, it has also left some damage in its wake; the pendulum seems to have swung the other way, and many infants are now kept on the breast indefinitely, when everything points to ultimate failure and in not a few cases to untimely death. It seems that the time is nigh for a note of warning to be sounded in regard to the limitations of breast feeding.

In regard to breast feeding several facts stand out pre-eminently:

1. To obtain a successful result, the breast feeding must be carried out in a scientific way and not in a haphazard way as it is usually practised. Many physicians believe that when breast milk is available, the mother should nurse the infant as frequently and for as long a period as the infant desires; this is due to the general belief that all breast milk is good milk. Few physicians realize that there are limitations even to breast milk. Breast feeding should always be advised and maintained in every case where it is of benefit to the infant, but in cases where it does not make the infant thrive, one should not hesitate to put such an infant on the bottle. This is no plea for artificial feeding, but we have often seen infants kept for so long a time on the breast without gain in weight and with resultant indigestion, that we find it of benefit not to wait too long before resorting to artificial feeding. Good breast milk is better than good artificial food, but good artificial food is better than poor breast milk.

2. If physicians devoted one-tenth as much time and attention to the study of the art and the science of breast feeding which they do to artificial feeding it is certain that the number of infants fed artificially would be reduced 100 per cent. When carried out properly, breast feeding presents very few difficulties; but when not so carried out it may present far greater difficulties than one encounters in feeding infants artificially. In the latter group of cases we can modify the milk in accordance with any symptoms which may be present; in breast-fed babies the composition of the milk can be modified but slightly (only the fat, and this not constantly), although the quantity can often be augmented by appropriate measures.

While ten years ago the worst feeding cases we saw were infants fed on proprietary foods, in the last few years, however, the number of infants suffering from marasmus as a result of improper breast feeding runs a close second to the above group of cases. To persist on the breast for weeks and months when everything points to ultimate failure makes artificial feeding in these cases difficult, and in many cases unsuccessful.

It sounds paradoxical, but it is true, that the hardest task we have before us is to persuade mothers not to institute artificial feeding when the milk supply is sufficient in early infancy, and to induce mothers to begin artificial feeding in later infancy, when the breast milk is very scanty and the infants are practically starving. In many instances this is due to the false impression the mothers have that they cannot become pregnant as long as they nurse.

Breast milk has a fairly uniform composition throughout the period of active lactation. The milk of the first few days (colostrum) differs from later milk in its higher caloric value, higher protein (mostly globulin) and salt content, and by the presence of transformed leucocytes, the so-called "colostrum bodies." The value of colostrum as a food for the new-born infant, is a question of great interest; it appears that the albumin of the blood and the albumin of the milk are biologically identical; the whey proteins of the milk are derived directly from the blood by filtration. Caseinogen, however, must be formed by the gland, either by a modification of the blood protein or derived from the gland cells; it seems that the colostral period is the transition stage for the infant from the period when it is nourished directly by the blood of its mother to the subsequent period when it depends on its own alimentary tract for nourishment. In this transition period (4 to 5 days) a different mechanism of absorption appears to be employed by nature; this method has for its object the tiding over of the infant from the intrauterine period to the period when it is dependent upon its own digestive juices; it seems that the proteins of the colostrum can be absorbed by the infant from its alimentary canal without undergoing any marked changes, whereas after the colostral periods the proteins must be broken down before they can be absorbed by the infant.

There is proof at hand that the mechanism which is concerned with the production of immunity appears to be intimately connected with the protein constituents of the blood; these properties are (in

milk) presumably attached to the proteins, and during the early days they can be transferred to the infant and can be found in the infant's circulation. Had the proteins been subjected to digestion along ordinary lines, the properties connected with immunity would almost certainly have been destroyed. This absorption, however, does not take place after the first few days of life; after the colostral periods the amount of protective substance found in the milk is generally greatly reduced. Our knowledge upon the transference of immunity by suckling demonstrates the possible value to the young of the colostrum of its mother.

The amount of immune bodies absorbed by nurslings appears to depend upon whether the immune properties are attached to a foreign protein or to the protein of the same species. It seems that foreign protein can be absorbed by the suckling in the early days of life, but that the absorption proceeds on a very much smaller scale than in the case of natural protein. The blood of the young of a mother who has been immunized does not at birth contain the immune substances of its mother; these are found after suckling has been established, although it has been shown that only a portion of the total amount present in the milk has been absorbed by the young animal as a result of suckling.

Breast milk contains from 1 to 1.5 per cent. protein. The most important proteins present are lactalbumin and casein. There are also present traces of globulin, opalasin, nuclein, and other nitrogenous extractives and vitamines (N-bodies). In breast milk, two-thirds of the protein is in the form of lactalbumin; in cow's milk, casein constitutes three-quarters of the protein in the milk. The casein of cow's milk has about three and one-half times as much phosphorus as breast-milk casein; the two caseins also differ in their way of precipitation with the acids: breast-milk casein separates into fine flocculi, whereas cow's-milk casein forms a heavy precipitate of large masses. This difference of precipitate is not due to differences in amino-acids, as they both contain the same amino-acids and in nearly the same amounts; when casein is not digested it passes into the stool, where it gives rise to hard, tough curds. These curds are not as tough in breast-fed infants as those found in stools of the artificially fed. The fat in breast milk varies from 1 to 8 per cent.; it is higher in the afternoon milk than in the morning milk, and it is highest at the end of every nursing (strippings). The foremilk is poorest in fat; it varies inversely with the quantity of the breast milk, the greater the quantity the less the fat percentage, and vice versa. Breast-milk fat has only 1.5 per cent. of volatile fatty acids, whereas cow's-milk fat has from 6 to 12 per cent. The glyceride of butyric acid is only found in traces in breast milk, and it is present up to 6 per cent. in cow's milk; breast milk contains more oleic acid. The sugar in breast as well as in cow's milk is lactose; it varies less in percentage than any of the other elements. The salts are less abundant in woman's than in cow's milk; with the exception of calcium phosphate they are dissolved in the whey. The calcium content is greatest in amount at the beginning of nursing, and diminishes toward the end of nursing; thus it acts in the reverse manner to the fat; as lactation proceeds, the calcium content of the milk diminishes. Rickets may develop in breast-fed infants despite the presence of a high calcium content in the milk. In fact, it has been found that the milk of mothers with rachitic infants has a higher percentage of salts than of those whose infants show no evidence of rickets. It has also been found that it is not possible to increase the amount of calcium in the milk by adding calcium to the mother's diet.

The chemical composition of breast milk is subject to certain variations. The chief characteristics of the milk of the colostrum period are the high protein and the high total ash. In the transition period (12-30 days) there is noted a striking reduction both in protein and in total ash, and a considerable rise in the fat. It appears that breast milk is richer in fat, protein, salts, and total solids, in the early weeks of lactation than at a later period. This corresponds to the needs of the infant during the period of his most rapid growth. In mature milk there is noted a fall in the total solids, which affects all the elements except the sugar, but is most noteworthy in the protein and ash.

Of all the ash constituents, the percentage of CaO continues most nearly constant throughout (except toward end of lactation); MgO shows wider variations; it is highest in the colostrum period and lowest in the transitional period; P_2O_5 does not show wide variations (somewhat higher in the colostrum and transition periods); Na_2O is highest in the colostrum period; in mature milk it falls to less than one-third of the amount; like Na_2O, K_2O is highest in the colostrum period; Cl runs parallel with Na_2O and K_2O. The high ash of the colostrum period is chiefly due to the higher values of Na_2O and K_2O. The only striking feature of late milk is a decline in quantity, though there is noted a slight fall in all the solid constituents except the sugar. The largest constituent of the ash of breast milk is K_2O; this and the CaO together make up more than half of the total ash.

Percentage Composition of Woman's Milk By Periods (Holt)

	Total Solids	Fat	Sugar	Proteins	Salts
Colostrum .... 1-12 days..	13.42	2.83	7.59	2.25	0.3077
Transition ....12-30 days..	13.39	4.37	7.74	1.56	0.2407
Mature .... 1- 9 months..	12.16	3.26	7.50	1 15	0.2062
Late .....10-20 months..	12.18	3.16	7.47	1.07	0.1978

Breast milk is the natural and the best food for the infant. One should never take an infant from the breast without sufficient and adequate reasons. In the first few days the quantity of milk secreted is very small, and the supply usually becomes more plentiful after the fourth day. However, the milk secretion may be insufficient for from two to three weeks and still under proper regime may become plentiful.

The milk secretion is excited by a reflex; the stimulus of the reflex is the nursing act. The more energetic and the more frequent is the nursing the greater is the quantity and the richer is the secretion. This amount can be enriched if the breasts are completely emptied artificially after nursing. In certain cases the milk secretion can be maintained for months through the artificial emptying of the breasts with a breast pump, even when there is no infant nursing. Thus, in acute illness of the mother, when it is advisable to take

the infant from the breast, the milk secretion may be kept up for a considerable time, and after the illness has subsided the infant may be put back to the breast.

If breast milk is allowed to stagnate in the breasts, as happens in cases of women who have abundant milk supply, but whose infants are weak and cannot empty their breasts, the milk supply is apt to diminish in quantity and the composition of the milk will revert to that of colostrum. Under these circumstances it is advisable to empty the breasts with the pump after the infant has nursed; or, what is still better, is to apply a healthy, robust infant to the breast after the first infant has nursed.

It is sometimes possible to renew the secretion of milk in a breast which has not secreted any milk for as long as eight weeks. Infants are often weaned without sufficient reason, and if there be any milk in the breast at all one should attempt to restore the supply of milk by instituting proper hygienic and dietetic measures for the mother and by applying the infant to the breast at regular and frequent intervals.

The amount secreted by the breasts is from 10 to 16 ounces in the 24 hours, at the end of the first week; it rapidly increases in amount, so that at the end of six to eight weeks there may be as much as one quart secreted; from the sixth to the ninth month the amount varies from 30 to 40 ounces; after this period the supply usually begins to diminish.

There is evidence at hand that as long as the nursing act is carried out so long the secretion of milk usually keeps up. Wet nurses, who nurse several infants during the day, and whose breasts are emptied with the breast pump immediately after nursing, usually secrete much more milk than the figures quoted above. A good wet nurse secretes from 1 2/3 to 2 2/3 quarts of milk a day. There are cases on record of wet nurses from whom as much as 5 or 6 quarts of milk were obtained in 24 hours. It has been shown that the mother's milk may be maintained for a considerable period by the mechanical emptying of the breasts; except in a few cases, the amount of milk obtained in this manner may be as plentiful as when the breasts are emptied by the infant. In early lactation, when the breast milk is insufficient, the artificial emptying of the breasts with a pump leads to an increased secretion of milk.

There are certain contraindications to nursing: (1) Tuberculosis. Any mother who has active tuberculosis of the lungs should not nurse her infant; moreover, the infant should not come in close contact with the mother, for fear of contracting the disease. Tubercle bacilli are not excreted through the milk unless there is tuberculous involvement of the breast. The danger to the infant is the tuberculous mother, and not her milk. Wherever possible, the infant should live apart from its tuberculous mother. (2) If the mother suffers from any chronic disease which affects her general condition the infant should be weaned (diabetes, uncompensated valvular disease, chronic nephritis, epilepsy, insanity, etc.). (3) If the mother has a severe, acute illness: in such a case the milk supply can be maintained for weeks by the regular emptying of the breasts. The infant should be only temporarily weaned, and after subsidence of the acute illness should be nursed again.

Erosions of the nipple are no indication for weaning; they usually respond to treatment with silver nitrate or compound tincture of benzoin. In cases of abscess of the breast, the infant should not nurse from the breast as long as pus is there; after the pus has been evacuated and, and granulations form, the infant should be put back on the breast.

The diet of a nursing woman should not be too limited. The woman should be allowed to eat everything she is accustomed to, provided it is not apt to disturb her digestion. A nursing woman should drink about 3 quarts of fluid every day, of which 1 to 1½ quarts should be milk. She should eat plenty of cereals, cooked fruits, meat and vegetables. There is no reason for not permitting sour flavors—fruits and salads. There is no reason, also, for not allowing a glass or two of beer a day or a little wine, if she is accustomed to it. Weak tea and weak coffee are also permissible. Generally speaking, unless you know that a food or beverage has a deleterious effect, it is permissible, if there be a craving for it, for under the circumstances abstinence is apt to do more harm than indulgence. Plenty of rest, sleep, exercise, and avoidance of all mental strain, are also indispensable adjuvants of successful maternal nursing. She should lead a regular mode of life, which should be simple and natural.

The quantity and the quality of breast milk are more dependent upon the amount of food ingested than upon the kind of food. When the total amount of food taken falls below the minimal daily requirements of the organism, either as a whole or in any of the necessary constituents, the milk tends rather to decrease in total amount than to show a deficiency of that particular constituent which is supplied in insufficient quantity in the diet. It has been shown that no appreciable increase in any one constituent can be attained by its addition to the food, even in large quantities. It has been found that the differences in composition of human milk are due to the individual women, and do not arise from the secretion of varying amounts of milk. If the amount of fat in the food is below the amount required for the usual metabolism, the amount of fat in the milk is reduced. The same is true of all elements. In other words, in underfed mothers the composition of milk depends on the nature of the diet, but in mothers who receive sufficient nourishment differences of composition in the milk are due to the individuality of the mothers.

It is certain that most mothers are underfed. If they only eat as much as they were accustomed to eat before the birth of the infant, and before pregnancy had taken place, they are bound to be underfed. A mother who secretes a quart of milk expends an additional 1,000 calories, which must be compensated by additional food, otherwise the milk is produced at the expense of body weight. It has been found that a nutritive ratio of 1:6 is best adapted to the needs of a nursing mother; that animal protein is more suitable than vegetable protein in supplying nitrogen for milk. A diet composed exclusively of cereals, fruits, and vegetables, does not supply sufficient protein for elaborating

milk protein, and causes a severe drain on the tissues of the mother. Of the various forms of animal protein, that which is derived from cow's milk seems particularly suitable for the production of human milk.

Both the quality and the quantity of milk can be influenced by outside factors; psychic disturbances, in particular, have a very strong influence on both the quantity and the quality of milk; the good effect on the mother of encouragement by the physician is frequently seen in an increase in the milk supply; with such encouragement, and with the institution of a proper regime, one will often succeed in mothers who had not nursed any of their previous infants. There are very few women who have not sufficient mammary gland tissue to nurse their infants at all. Women will often say that they could not nurse any of their eight or more previous infants. Such statements should not influence the physician from trying to institute breast feeding in the particular case. With proper encouragement and proper measures we have been able to institute and to carry out successfully maternal nursing in many women who had not nursed any of their previous infants. In one instance we persuaded a mother who had nursed only the first of her 19 children—18 of whom are dead—to nurse her twentieth infant, and with the institution of a proper regime she succeeded in nursing this infant for 8 months. The twentieth and the first are the only living children she has now. Certain mothers have an obsession that they cannot nurse their infants, and only too frequently and too readily do physicians coincide with these ideas of the mothers. It is the sacred duty of the physician to disillusionize these mothers of their preconceived ideas and to encourage them to nurse their infants. A mother may not have been able to nurse her previous infants for any number of reasons, but this is no excuse for not nursing her present infant.

Menstruation of the mother is no cause for weaning. We have never had to wean infants on this account. Certain infants present slight gastrointestinal symptoms which recur with every menstrual period, and show slight loss of weight, but they do perfectly well, and make up in weight after the first two or three days of the menstrual period. Many infants show not the slightest disturbances during the mother's menstruation; in most cases, the only change observed in the breast milk at this time is a temporary diminution in quantity.

Pregnancy is not an absolute cause for weaning. If the mother is robust, and the infant is puny, we allow nursing in gravid women for three or four months. I have never seen any bad results follow such a procedure; miscarriages have never occurred. Moderate sexual intercourse has no influence on the milk secretion; excessive intercourse undoubtedly has a deleterious influence on the milk supply by affecting the nervous condition of the mother.

Certain drugs taken by the mother may be eliminated in the milk—morphine, belladonna, bromides, iodides, arsenic, saline cathartics, etc.

The immunity of breast-fed infants to certain infections is usually attributed to antibodies and other protective substances supplied to nursing infants through mother's milk. Certain antibodies are found in mother's milk (*e.g.* those of diphtheria and typhoid), but whether immunity of breast-fed infants depends entirely on these and other antibodies, and not on the high state of nutrition of breast-fed infants, is problematical. Artificially-fed infants who have been fed properly from birth show no less resistance. We are inclined to believe that resistance to infection is more dependent on the nutritional condition of the infant than on the mere fact that the infant is breast fed or not. Breast-fed infants with nutritional disturbances have no greater resistance to infection than artificially-fed infants. The formation of antibodies depends more on the state of nutrition of the body, and there is no reason to suppose that an infant who received a properly balanced artificial diet should not have a normal resistance; and, as a matter of fact, they have. This is no reason for not encouraging nursing in every case; breast milk is the natural food, and to bring up an infant properly on the breast is a much simpler task. The resistance of infants depends to a large extent on the nature of combination of the water in the body: if it is a loose combination, the resistance is low; if in more permanent combination, it is greater; but this in turn depends on the state of nutrition. The metabolism of water constitutes one of the most important phases of an infant's metabolism; they can withstand hunger much longer than they can thirst.

Proper technique is most essential for successful breast feeding. The physician must instruct the mother as to proper clothes for herself, as to cleanliness of the breasts, and in what position to hold the infant during nursing. She must be careful to see that the pendant breast does not obstruct the nares and thus make nursing difficult. This is obviated by her pressing the breast back with two fingers of the other hand, open scissors fashion. She must be told to insert part of the areola with the nipple in the case of an infant who sucks up considerable air, and she should be told to express the first few drops of milk with her fingers, because this part is usually contaminated with bacteria. Washing off the breast before and after nursing with plain lukewarm water in which is dissolved some boric acid, should be insisted upon. A pad of sterile gauze should be applied after nursing.

In the first 24 hours after birth the infant should be applied to the breast every six hours. If the infant obtains but little colostrum, plain boiled water, lukewarm, without sugar, should be given immediately after nursing.

We are convinced that no hard and fast rule can be followed as to the intervals observed in the feeding of infants at the breast; a number will thrive on five nursings, others will require more; each infant must be studied separately in regard to the number of nursings. However, we believe that most breast-fed infants will do well on six feedings in the 24 hours (with 3½-hour intervals during the day, and no feeding between 10 P. M. and 6 A. M., after the second month). One should always see that the infant obtains enough fluid during the day; unless he receives sufficient fluid he is apt to have a rise in temperature (thirst fever).

In the next 24 hours the infant should be put on the breast every 4 hours; at the end of the first week it should be put to the breast regularly every

3½ hours; no infant should receive more than 7 feedings in the 24 hours. Robust infants, whose mothers have a large quantity of milk should have longer intervals (4 hours), and fewer feedings (five or six). No nursing infant should receive the breast more often than every 3 hours. The infant, if asleep, should be awakened at its regular feeding time; very soon it develops the habit of waking at the regular feeding time.

No infant should be allowed more than 15 minutes at a breast feeding; the infant receives most of the feeding in the first five minutes; but as the last milk contains the most fat, he should be allowed to express the rich milk. The infant should not nurse from both breasts at one feeding, if the mother has an abundant milk supply; however, if the milk supply is not abundant, the infant should be allowed to nurse from both breasts at each nursing. The more thoroughly and the more frequently a breast is emptied the greater will the milk supply be. In cases in which the milk is abundant the mother should alternate breasts at the different nursings.

On the average, breast-fed infants take at the end of one week 1 1/3 to 1 2/3 ounces at a feeding; at 1 month, 2 2/3 to 3 2/3 ounces; at 3 months, 4 to 4½ ounces; at 4 months, 5 ounces; at 5 months, 5½ ounces; at 6 months, 6 ounces. A very robust infant will not infrequently take as much as 10 ounces at a feeding. At the end of one week, breast-fed infants take about 15 ounces of milk in the 24 hours; at the end of 1 month, about 20 ounces; at 2 months, 26 ounces; at 5 months, about 30 ounces. Only in exceptional cases does the amount taken exceed 1 quart. It thus appears that a breast-fed infant takes about one-fifth of its weight of milk in the first 2 months of life (45 calories to the pound); one-sixth to one-seventh from the second to the sixth month (40 calories to the pound); and about one-eighth its weight in milk from the sixth to the twelfth month (30 to 35 calories to the pound).

Wet Nurses.—When a mother is not able to nurse her own infant, a wet nurse, if available, should be obtained. A certain number of artificially-fed infants with nutritional disturbances can be saved only by wet nurses. In selecting a wet nurse, we must be careful to select one that has no trace of syphilis and tuberculosis. A Wassermann reaction should be carried out on both the wet nurse and the infant to protect the infant to be nursed as well as to be certain that the infant does not infect the nurse and her child. A complete physical examination of the nurse, including the urine and a vaginal smear, should be made. To be sure that the milk supply will be plentiful it is best to select one whose infant is at least one month old; disparity in age between the nurse's infant and the one to be nursed does not matter. The best criterion whether a wet nurse has sufficient breast milk of good quantity is the appearance of her own infant. When her own infant cannot be seen, the wet nurse is to be judged by the appearance of the breast and by the examination of the milk.

A good wet nurse is one whose breasts become soft after nursing, and are full and tense at the next nursing time; the breasts should not be knotty or too fat. The amount of fat and mammary gland tissue do not go hand in hand; a small breast may secrete much milk, and a large breast may secrete little milk. A wet nurse should be between 20 and 30 years of age, and one who has nursed a previous infant is to be preferred. The new surroundings and duties of a wet nurse may lead to a temporary diminution in the quantity of the milk. Nurses who suckle puny or weak infants should empty their breasts after nursing the infants, either by the nursing of another and robust infant, or by means of a breast pump; otherwise, the milk secretion is apt to decline rapidly, for anything which leads to stasis of breast milk will eventually lead to its entire disappearance.

Mixed Feeding.—When breast milk is insufficient, we have to resort to mixed feeding. Every breast-fed baby should be taught to take water from a bottle; this procedure makes weaning, when necessary, a simple matter. If the mother is an intelligent woman, and there is no fear that she will neglect nursing, there is every reason why a breast-fed baby should have one nursing substituted by a bottle feeding; this enables the mother to have at least a six-hour rest, and permits her to attend to whatever social duties she may be called upon to perform. This bottle feeding should be composed of half milk and half water (the sugar to be made 6 per cent.); the quantity to be given depends on the age of the child.

When there is insufficient breast milk, and breast milk must be supplemented by artificial feeding, it is better to prescribe "complementary feeding" (that is, bottle feeding immediately after nursing) than "alternate feeding" (that is, an exclusively breast feeding is followed at the next regular feeding time by an exclusively bottle feeding); the rationale of this procedure has been previously discussed. In cases where the mother has to work during the day, alternate feeding must be instituted. The mother should, however, be advised to empty her breasts with a pump at least twice during the day. Unless this procedure is carried out the milk secretion soon diminishes in amount, and very shortly disappears entirely. In these cases the mother should nurse her infant before she goes to work, at 6 or 7 A. M., and at 7 and 10 P. M., when she returns; during the day the infant should receive bottle feeding at 10 A. M., 1 P. M., and 4 P. M.

Weaning.—In early infancy one must be especially careful not to wean an infant without very definite and very sufficient reasons. The disturbances in the milk secretion, both in quantity and in quality, in the first few weeks after parturition are usually only temporary. However, when we are convinced that the infant must be weaned we must not hesitate to do so at the earliest moment. There are mothers whose milk is of sufficient quantity, and of good quality, but their infants do not thrive on their milk; in these we should not try to keep the infants on the breast any longer than two or three weeks.

Very few mothers of the working class can nurse their infants longer than seven or eight months, and there are no good reasons for prolonging lactation beyond this time in the majority of cases. The milk secretion usually becomes insufficient at this time (at seven or eight months). We have been in the habit of weaning infants at this age, who for

two or three weeks in succession failed to gain in weight or lost in weight, when there was nothing to be found on physical examination to account for this.

When breast milk becomes insufficient at this age we have a choice of weaning entirely or partially, or of adding other food, like cereals, to the breast feeding, without the addition of cow's milk. We have fed a large number of babies in all these ways, and have come to the conclusion that breast-fed infants (in later infancy) who are weaned entirely when the breast milk becomes insufficient do much better and weigh more at the end of the year than when they are fed in either of the other two ways. If these infants are continued on the breast to the end of the year they are usually overfed and fed too frequently; they very often receive the breast at all hours during the day and whenever they cry at night; only in the case of very puny infants do we continue the breast milk to the end of the year (after it has become scanty). In well-nourished infants there is nothing to gain and much to lose by adopting such a procedure.

Weaning should always be carried out gradually. If the infant is under nine months it should receive its food from a bottle; if over nine months, from a cup. When weaning, we begin with a one-third milk and two-thirds water mixture; the percentage of sugar should be 7 (preferably granulated sugar). As breast milk is very sweet, infants often refuse a milk mixture on account of its taste; it is, therefore, never advisable to use dextrinmaltose in weaning infants. The quantity at a feeding is determined by the age and the weight of the infant. There are absolutely no reasons for not weaning infants in the summer time, if indications for it are present and a clean milk can be obtained. We have never seen any bad results follow weaning in the summer time.

We begin to wean by substituting one of the breast feedings with a bottle or cup feeding every third day, until the infant takes six artificial feedings; then the milk formula is strengthened. When the infant takes whole milk, cereals and later broths are added; the broths contain finely mashed vegetables (peas, beans, carrots, potatoes, spinach). Orange juice should be given at five to six months; earlier, if there is a tendency to constipation. No infant is too young for orange juice. At seven months, beef juice (½ to 2 ounces) or the yolk of egg (hard boiled for 30 minutes), crackers (milk, zwieback, arrowroot) should be allowed at six to seven months.

In the majority of cases, weaning is a simple matter; in a few it cannot be accomplished gradually, because as long as the breast is given the child refuses the bottle (some of those who refuse the bottle will often take fluid from a cup or spoon); in these cases, weaning must be sudden, but the formula which is ordered must be weaker than the one prescribed to infants weaned gradually. Certain infants absolutely refuse to take the bottle or cup for a good many hours; in these cases the milk (or water, if they refuse to take the milk) should be offered to the infants regularly every three hours, but never before the next regular feeding time, until it is taken. At times an infant will refuse to take all nourishment for from 24 to 48 hours, but when it does there is no further trouble. In all these cases it is essential to starve them into submission, but plenty of water must be given. In difficult cases the mother cannot be depended upon to carry out the strict starvation which is necessary to curb refractory cases, for they will give them the breast when the crying of the infant is at all excessive. In these cases a trained nurse can accomplish more in twelve hours than a mother can in a week.

Digestive and Nutritional Disturbances in Breast-Fed Infants.—Before condemning the milk of a particular woman, the physician should always be sure that he is dealing with a healthy infant. A complete physical examination should precede any change in the diet; one should always be sure that there is no constitutional disease present to account for the lack of gain in weight or for the presence of gastrointestinal symptoms.

1. Of all the diseases which may keep a breast-fed infant from thriving, even when the milk supply is plentiful, the two most important are pyloric stenosis and the exudative diathesis. One should always suspect the presence of a pyloric stenosis in a breast-fed baby who suffers from projectile vomiting, whose mother has a plentiful supply of milk, and when the technique is faultless. This symptom should always lead the physician to examine the abdomen of the infant for visible peristalsis and pyloric tumor.

In the presence of early symptoms of seborrhea, eczema, intertrigo, frequent attacks of bronchitis, adenitis, exudative inflammation of the mucous membranes of the eyes, nose, throat, pharynx, or intestines, in a breast-fed infant who is not gaining sufficiently, or at all in weight, even when the breast milk is abundant, one should always suspect the presence of the exudative diathesis. These infants are particularly characterized by their low resistance to infection and by their tendency to run temperatures without apparent or for very slight causes. Some of these infants are fat, and others, on the contrary, are thin. The latter fail to gain on sufficient diet, the former put on weight on insufficient diet; many of these infants show evidences of a weak nervous system. The digestive disturbances which these infants show are usually due to a diminished tolerance for fat; the stools are usually loose, and this leads to an increased loss of fat and protein in the stools; the limit of tolerance for sugar seems also to be diminished; chlorides are retained in more than normal quantities, and this leads to increased water retention and diminished resistance to infection. While both these types do not do well on the breast in early infancy, they do worse on artificial feeding, and should, therefore, not be weaned in early infancy unless they are losing in weight. In the fat type, we should attempt to diminish the gain by increasing the intervals, by allowing the infant to nurse only for five minutes at a time, and by removing the strippings (rich milk) with a pump. In the thin type, after sufficient trial on the breast, mixed feeding should be attempted; of special benefit in these cases is fat free milk or eiweiss milk; these cases often do better on artificial feeding than on the breast.

There is a small group of infants who are born with a diminished tolerance for fat, but who do

not necessarily develop any symptoms of exudative diathesis; on the contrary, as they grow older they develop a tolerance for normal amounts of fat. These infants should not be weaned; they should be treated as the infants of the fat type with the exudative diathesis.

Occasionally we meet infants who are born with a very irritable and easily exhausted nervous system; very often these infants do not thrive; even the mere act of nursing seems to exhaust them; frequently they have gastrointestinal symptoms; even when the breast milk is good and the technique is perfect they frequently have loose stools of green color and poor in substance. Peristalsis in these cases is increased, and may be painful; regurgitation and vomiting are usually present. These symptoms are not infrequently associated with symptoms of the exudative diathesis. The diagnosis of these cases is based on the presence of the following symptoms: restlessness, diminished and disturbed sleep, frightfulness, anorexia (marked), vomiting, and diarrhea, without apparent cause, and vasomotor symptoms (sudden pallor or flushing). These symptoms make their appearance in the presence of an abundant milk supply and in the absence of all infections; there is usually a neuropathic family history. These infants should never be weaned; the home life should be regulated, the infant should have absolute quiet, and should be free of all irritation and "showing off"; it should be handled by only one person (preferably a trained nurse), and not much by this one.

The physical examination may reveal the presence of some constitutional disease, as tuberculosis, lues, etc.; these should be treated accordingly. If the infant has tuberculosis, and the mother has not, it should not be weaned; it has a much better chance of surviving if it is breast fed (but in the great majority of cases the infant becomes infected by the mother). An infant with lues should never be weaned. If a new-born infant is syphilitic, its mother is invariably so, too. At times, luetic infants do not thrive even on the breast, on account of insufficient treatment, and they do much worse under these circumstances on the bottle. A luetic infant should receive thorough antiluetic treatment, if success is desired.

2. The breast milk may be of good quality and of sufficient quantity, and yet the infant may not thrive: (*a*) On account of general weakness of the infant (the infant too weak to express the milk); (*b*) on account of undeveloped suction power; (*c*) because the breasts are emptied with difficulty; (*d*) on account of shyness of the breast; (*e*) because of the presence of hare lip or cleft palate; (*f*) because of inverted or otherwise malformed nipples; (*g*) by reason of the presence of adenoids.

When the infant is too weak to obtain the milk, the latter should be expressed with a pump and then given with a spoon, pipette, Berk feeder, or by a tube (through the mouth or nose); the secretion of milk may be maintained for months in this way. It is important that the breast should be completely emptied, otherwise there is a gradual tendency for the milk secretion to diminish in amount. When possible, a healthy, robust infant should be applied to the breasts to empty them, after the milk has been obtained with a pump.

In shyness of the breast the infant must be put to the breast more frequently until he is broken of the habit; at times, a little sugar solution on the nipple will entice it. I have known many mothers to put castor oil on the nipple as an inducement to faltering infants, with good results; most infants love castor oil, and lick every drop of it from the nipple.

Infants with harelip and cleft palate should be operated on at about the third or fourth month of age if their condition is good; when these defects are so marked that the infant cannot create sufficient vacuum which is essential for suction, it should be fed as described above for weak infants.

Marked inversion of the nipples makes nursing impossible, because the infant cannot grasp the nipple; one should not resort to artificial feeding in these cases before trying a nipple shield; very often with the aid of a nipple shield and by expressing the remainder with a breast pump, many of these infants can be partly breast fed for months. In every case of inverted nipples, the breasts should receive attention before the birth of the infant; at times, with proper manipulation, the inversion may be corrected so that the infant can nurse; at least part of the nipple may be made to project, so that the infant by grasping this part and the surrounding areola may carry out the nursing act. In a number of cases I have seen inverted nipples sufficiently corrected by the use of a clay pipe, or small suction cup applied over the nipple, suction being applied at the other end.

The presence of adenoids in the newborn may hinder nursing because when the infants nurse they cannot breathe; I have removed adenoids in infants as young as two weeks (and would not hesitate to do so in the first forty-eight hours of birth if indicated) with excellent results; all symptoms of nasal obstruction, stridor, asthmatic attacks disappeared; in the presence of adenoids, these infants cannot nurse more than 2 or 3 seconds at a time; they become exhausted and lose weight; the difficulty in nursing disappears immediately after adenectomy; the other symptoms subside within 2 or 3 weeks. Under no circumstances should an infant be weaned on account of the presence of adenoids.

3. Very often breast-fed infants do not thrive because the technique is not perfect; thus: (*a*) infants often fed too frequently or infrequently; (*b*) for too long or too short a period at each nursing; (*c*) too many or too few nursings; (*d*) nursed irregularly; (*e*) fed from both breasts at each nursing; (*f*) abuse of pacifiers; (*g*) too much handling.

No infant should be nursed more frequently than every 3 hours; and many do better on 3½ to 4-hour intervals; no infant should be nursed more than 7 times in the 24 hours, and no infant should receive any night feeding after the second month; no longer than 15 minutes should be allowed at a nursing; very often when they nurse longer they expand more energy in obtaining the little milk, which they express, than is the caloric value of the milk expressed; thus, I have seen infants who weigh less after nursing than before (especially in cases of insufficient milk or in cases of breasts which are emptied with difficulty). Irregular nurs-

ing is apt to disturb the secretion and the composition of the milk and usually leads to digestive disturbances. When the milk supply is abundant, the infant should be nursed only from one breast; when the infant is nursed from both breasts neither breast is completely emptied; this leads to stasis and diminished secretion of milk. Pacifiers should never be allowed; they are apt to carry infection, and almost invariably cause colic, vomiting, the swallowing of much air, and all the symptoms associated with this. An infant should be held up immediately after nursing and gently patted on the back or abdomen to facilitate the expulsion of the air; too much handling or bouncing or "showing off" of the infant should be avoided, as it is apt to cause vomiting, and makes the infant irritable and nervous.

4. In cases where the physical examination of the infant reveals no cause for the malnutrition, it should be sought in the mother. (*a*) It may be due to an insufficient amount of milk (quantity sufficient but quality poor—of sufficient caloric value, but water content inadequate—quality good but insufficient quantity); (*b*) milk too rich or too abundant (quantity too great—fat too high); (*c*) milk unsuitable for the infant (improper percentage composition—percentages may be proper and still the milk may not be suitable for the infant.

Before we discuss the various phases of this subject, we must digress to acquaint ourselves with the symptoms of underfeeding and of overfeeding in the infant.

An infant who is underfed does not gain in weight; he is always hungry; his appetite is good; he is restless, cries much, does not sleep sufficiently nor deeply; he very often vomits on account of the constant agitation through hunger; when nursing he hangs on to the breast for ½ hour or longer and then drops the nipple only from mere exhaustion; later, when he has learned that there is not much milk in the breasts, he makes a few attempts at nursing, and then drops the nipple in disgust; the bowels are usually constipated; when the underfeeding is extreme, we have the starvation stools (dark in color, tenacious, sparse); at times when the breast milk is insufficient it is also of inferior quality and this may lead to 4 or 5 green loose stools; in severe cases, the temperature is subnormal and the pulse slow; if the water need of the infant is not covered, the temperature may be very high (104°—105° Fahr.).

An infant who is overfed may for a time be gaining in weight; this may mislead one unless he carefully weighs other symptoms; most physicians attach too much importance to weight and too little to gastrointestinal symptoms. The appetite is poor; the infant nurses for but a few minutes, and is usually not hungry at the next regular feeding time; if it is due to too high fat in the food, vomiting is present; if the vomiting is excessive the bowels are constipated otherwise they are loose, due to excess of fatty acids in the intestines; tympanitis and colic are usually present; the abdomen is distended, whereas in underfed babies it is usually retracted; the temperature is apt to be elevated. Overfed babies are usually fat and are subject to skin eruptions (eczema, intertrigo, furunculosis) and usually have a diminished resistance to infection. When vomiting and loose stools are present there is no gain in weight and they may even lose weight. General symptoms of restlessness, disturbed sleep, excessive crying (colic) are always present; in severe cases, the temperature is elevated and lactosuria is present.

When we suspect that an infant is underfed, the best way to determine this is by observing the child on the breast alone for one week, noting the weight at the first and the second visit; in all these cases we must see that plenty of water is given during this period of observation; weighing the infant before and after nursing is not a reliable method; because the quantity of milk secreted and the amount taken by the infant at different nursings vary greatly; thus one may obtain an entirely erroneous opinion from such a single observation. In these cases, when under observation, we instruct the mothers as to mode of life, diet, and proper technique of nursing; the quantity of milk secreted may be augmented by increasing the amount of fluid taken (especially milk, 1—1½ quarts), by adding cereals to the diet (especially cornmeal), and by the prescribing of certain galactagogues, especially maltine or a glass or two of beer a day; the mother should have a chance to rest every afternoon for two or three hours, and should have plenty of sleep during the night. In most cases the institution of these measures will bring about the desired result; one should never be in too great a hurry to institute complementary or supplementary feeding in these cases; moreover, one should never take a mother's word for the fact that her milk is insufficient. Mothers very often imagine that they have an insufficient supply of breast milk when it is abundant and the infant is thriving and is robust; to a mother an infant's cry invariably means hunger; in these infants the crying is more often due to overfeeding; an infant who receives insufficient breast milk usually cries a good deal, nurses for from one-half to three-quarters of an hour and then must practically be torn away from the breast; it stops nursing only from extreme fatigue; on the other hand, an infant that nurses a breast which has a rich and plentiful supply of milk usually nurses for a very few minutes and then falls asleep.

When we find that by treating the mother we cannot influence the amount of milk we must complement the breast milk with artificial feeding; one should not be in too great a hurry to resort to mixed feeding for it usually means that within two or three months the infant will be entirely weaned; one therefore should try to increase the mother's milk by proper diet and hygiene and should keep the infant for at least two or three weeks on the breast alone, before resorting to mixed feeding. Of course, one must use his judgment in every case; this is not an arbitrary rule which can be followed blindly; in cases where there is hardly any breast milk and no improvement is noticed, one cannot wait too long; in all these cases plenty of water should be given.

When we are finally convinced that mixed feeding is absolutely necessary we have a choice of adding artificial feeding immediately after nursing or alternating nursings and artificial feedings. From our knowledge that the more frequently a breast is stimulated to secretion the more milk will be se-

creted, we are convinced that giving a bottle immediately after every nursing has advantages over alternate breast and bottle feeding. The quantity to be given at each feeding is determined by weighing the infant before and after nursing for two days and taking an average of the quantities which the infant consumes at each feeding. The quantity which should be given in the bottle should be sufficient to make up the necessary quantity which an infant of that age should receive; if an infant 3 months old obtains about 1½ ounces of breast milk at each nursing, we should prescribe about 2½ ounces to be given in the bottle after feeding. One should continue to weigh the infant before and after nursing and if at any time the breast milk becomes sufficient the bottle should be discontinued; there is always a tendency to overfeed infants on mixed feeding by giving them too much in the bottle; the result is they are not very hungry at the next feeding time and they do not take the breast readily; as a result of this there is insufficient emptying of the breast, stagnation of milk, diminished secretion, and finally no more secretion of milk takes places. Infants under these conditions very soon learn that it is easier to obtain the milk from a bottle than from a breast which has a scanty secretion and very often under these circumstances they soon refuse to take the breast at all, and have to be entirely weaned. Infants who take a little breast milk can usually digest stronger mixtures of cow's milk than those who do not take any. We therefore put these babies on half milk and half water mixtures, and make the carbohydrates 7 per cent.; infants who receive breast milk often refuse to take the bottle because the mixture is not sweet enough; breast milk is very sweet; therefore we always use cane sugar under the circumstances, and make the percentage of sugar 7.

In cases where the quantity is sufficient but the quality is poor, the amount of fat in the milk may be increased by increasing the amount of nourishment which the mother takes, by the addition of a glass or two of beer, plenty of cereals with butter, plenty of milk, plenty of rest (day and night), plenty of fresh air, by reducing her exercises, and by prescribing massage of the breasts and tonics if her condition is below par.

When the breast milk is of sufficient caloric value, but is deficient in water content, this deficiency can be compensated by the administration of water from a bottle immediately after every nursing.

Overfeeding may be due to too high fat in the milk or to too great quantity. If due to too high fat, all alcohol should be stopped, the solid food should be reduced; exercises, such as walking, should be increased. The intervals between nursings should be increased, the time allowed at each nursing should be shortened, and the strippings or high fat milk should be removed with the breast pump and discarded. If the symptoms are due to the taking of too great quantities, the infant should be allowed to nurse only for 7 or 8 minutes at a time; but in these cases the fore-milk and not the strippings should be removed (from 1 to 2 ounces, depending on circumstances); the rationale of this is to give the infant the milk of high caloric value, and so that it can empty the breasts, which is essential for continued secretion of milk; the intervals should be lengthened, because the less frequently a breast is nursed, the less is the amount of milk secreted. The prospects of success, when the milk is too rich, are far better than in cases with poor milk.

The breast milk may be of sufficient quantity and yet may be unsuitable for the infant; in some cases this may be due to low total solids in the milk; in others to indigestibility of certain elements of milk brought about by nervous influences working on the mother (shock, worry, fright, moving pictures); and, in still other cases, the quantity and the quality of the milk reveal no deviations from the normal so far as chemical analysis reveals, the technique is perfect, and yet the infants fail to thrive, although they do not suffer from any diathesis or constitutional disease.

When an infant who had been thriving steadily suddenly develops digestive symptoms, we must carefully enter into the history of the mother's diet and mode of life; the diet, the social life, the habits and the mental state all have a tremendous influence on the quantity of milk secreted and on the digestibility of certain of its elements; in certain mothers overwork, worry, anxiety and fright have an immediate effect on the quantity and the digestibility of the milk; the indications for treatment in these cases are apparent; still, there are infants who are not affected to the slightest degree by any worry, fright, anxiety, or overwork on the part of the mother, nor by what the mother eats, nor by the condition of the mother's bowels.

In cases in which the breast milk does not agree with the infant we should make all attempts (for 2 or 3 weeks) to modify the milk by appropriate measures and in accordance with the chemical analysis of the milk; if at the end of this time we are not successful in modifying the milk in the desired direction, we should not hesitate to wean such an infant; to persist too long in keeping it on the breast when all signs point to failure is to court marasmus; some of the worst cases of marasmus seen are the result of improper breast feeding.

In cases due to underfeeding all attempts should be made to increase the milk supply of the mother. In early infancy insufficiency of breast milk is not infrequently met with. In the great majority of cases it is only temporary; the cases which do well under these circumstances are those in which the breast milk, under proper régime, becomes more plentiful. Every ounce of breast milk should be conserved and utilized if it is good. An infant who receives even a little breast milk (if it is good) can digest cow's milk much better than one entirely artificially fed; but as everything that glitters is not gold, so everything that comes from the woman's breast is not good milk. The idea is prevalent that all breast milk is good; this is not a fact. There are mothers whose milk contains the right percentages of its elements and in whom the quantity of milk is abundant and yet their infants do not thrive although they have no constitutional disease or diathesis to account for such lack of progress. This is most apt to occur in cases where the breast milk is insufficient. These infants do not do as well on mixed feeding as on the bottle alone. In every case of insufficient breast milk and in cases where the quantity is abundant and the quality is good,

but the infants do not thrive, we should try to keep the infants on the breast alone for 2 or 3 weeks, if the symptoms are not severe, and observe them frequently. One should never be in too great a hurry to resort to mixed feeding nor to wean an infant without sufficient and adequate reasons; however, when we are convinced that the breast milk is insufficient we should resort to complementary feeding (that is, bottle feeding, immediately after nursing); if the infant's symptoms subside and it begins to gain in weight, we should continue both the breast and the artificial feeding. Very often in cases of insufficient breast milk, when complementary feeding is instituted, one obtains a history that the infant vomits every time it takes the breast but that it retains the bottle feedings; very often these babies also have 3 or 4 green stools a day; in these cases one should not hesitate to wean them entirely; the good effects which are often immediately seen are very striking. In the second group of cases one should not hesitate to wean the infants entirely also, after sufficient trial on the breast, if they do not thrive. In these cases the quantity is plentiful and the percentages are right, but the milk is not the right milk for the babies. In breast-fed as in artificially-fed infants we cannot make the babies fit the milk, but must make the milk fit the infants.

Analysis of mother's milk is often without value in determining why a certain milk does not agree with a particular infant. Our knowledge of breast milk is still rudimentary; at present we possess only a fairly accurate knowledge of its chemical composition; it seems that under certain circumstances, normal elements of milk assume abnormal properties, or that certain substances make their appearance in breast milk, the nature of which is unknown, but which, nevertheless, exert a most important influence on the infant's digestion and nutrition; the presence or absence of these bodies (x-bodies) at times determines whether a certain milk is or is not suitable for a particular infant. In the great majority of cases the milk of its own mother is the best and most suitable food for the infant; however, there are infants whose mother's milk contains the right percentages (as far as chemical examinations can determine), and the quantity is abundant, and yet who fail to thrive, although they suffer from no constitutional disease or diathesis; and on the contrary specimens of breast milk have been examined which showed them to be grossly deficient in certain elements and excessive in others, and yet the infants were thriving properly. That there are differences in breast milk is also proved by the fact that the same infant behaves quite differently on the breast of different women. All infants have not at birth the same power to digest the same percentages of fat, sugar, and proteins, and it is possible that the cause of malnutrition in these cases may be an innate intolerance for certain elements; but these infants with diminished tolerance overcome this intolerance, even when retained on the breast; the cases under consideration here, however, are those in which we cannot influence the mother or her milk in any way, and the infants must inevitably be weaned if success is desired. I have never found any difficulty in feeding these infants artificially.

Examination of the breast milk will at times reveal why the milk does not agree with the infant (high fat or low total solids), but in these cases one can usually arrive at the correct conclusion from a consideration of the clinical symptoms. It appears to us that the chemical examination of milk is but seldom of any real assistance in determining the quality of breast milk; any one who will persist in nursing an infant who is not thriving, because the analysis of the milk shows it to be of normal chemical composition, is bound to meet with dire consequences. After all, the best way of determining the quality of breast milk is clinically; a good breast milk is one which makes the infant thrive; an unsuitable breast milk is one which does not make the infant thrive, no matter what its chemical composition is. It is evident that the infant is more than a test tube, and that biological principles must be considered.

5. A sudden onset of a nutritional disturbance (in a breast-fed child who has been doing well, and in whom the technique has been carried out perfectly) should always lead one to suspect the presence of some infection, to which the nutritional disturbance is secondary; in most of these cases it is due to parenteral infections, as pyelitis, influenza, etc.; in others the infection is enteral. Vomiting is a prominent symptom in these cases; the high temperature is often in marked disproportion to the slight gastrointestinal symptoms; these infants often cannot nurse well owing to catarrhal nasal obstruction; they should never be weaned. The symptoms usually subside after the disappearance of the infection, although anorexia persists for some time afterward. In enteral cases the indications for treatment are, catharsis, starvation, gradual return to full nursing (plenty of water must always be given).

6. The nutrition of breast-fed infants may also be affected by overheating, chilling, lack of fresh air, anemia, improper clothing and bathing; to obtain results one must attend to all these factors.

The symptoms of nutritional disturbances in breast-fed infants, may be very mild at first, but if the causative factors are not corrected early they slowly but surely lead to serious consequence (marasmus, intoxication). One of the first symptoms to be noted is a capricious appetite and later anorexia; general symptoms (fretfulness, restlessness, insufficient and easily disturbed sleep, excessive crying) soon make their appearance; the infant may still be gaining in weight in this stage and this may mislead the physician. Later, symptoms referable to the gastrointestinal tract develop, such as regurgitation, vomiting, colic, tympanitis, constipation, or loose stools; in this stage the weight is stationary or there is loss of weight. If the causative factors are still not corrected, constitutional symptoms make their appearance; these are: disturbance of temperature (with high fever, alimentary fever, or there may be subnormal temperature); lactosuria; vasomotor disturbances; diminished resistance to infection; tendency to inflammations of the skin and mucous membranes; anemia; diminished muscular tone. In brief, we may have a complete picture of marasmus or intoxication, depending on the nature of the disturbance.

Infants with digestive and nutritional disturb-

ances may be divided into 3 groups, depending on the severity of the disturbance:

1. There is gain in weight, but there are present gastric or intestinal symptoms.

2. There is insufficient gain in weight, but (*a*) no symptoms are present; (*b*) with gastric symptoms; (*c*) with intestinal symptoms; (*d*) with gastric and intestinal symptoms.

3. There is stationary or loss in weight, (*a*) with gastric symptoms; (*b*) with intestinal symptoms; (*c*) with gastric and intestinal symptoms; (*d*) with gastric, intestinal, and constitutional symptoms.

The symptoms which the infants in the first group may present are anorexia, regurgitation, vomiting, rumination, colic, tympanitis, constipation, loose stools. While many of these infants continue to gain in weight in spite of these symptoms, it is never advisable to disregard their presence for any length of time; the physician should make every attempt to relieve and mitigate these symptoms as soon as they arise; the aphorism, "A Stitch in Time Saves Nine," has no better application than in infant feeding; neglect or total disregard of these symptoms may often lead to serious complications. In a majority of cases, the symptoms are due to faulty technique, underfeeding, or overfeeding. A consideration of some of these symptoms is important.

Rumination is a neurosis; there is no anatomical basis for it; *x*-ray examination of the stomach in these cases reveals normal position, form, and motor function; it is more common in females; it is influenced by psychic disturbances, intercurrent diseases, and other factors, but very little by drugs. The prognosis in cases without dyspeptic symptoms is good. Semi-solid food is uncertain but should be tried (gruels); usually there is improvement toward the end of the first year.

Regurgitation, "spitting up," is not infrequently met with in healthy infants; in fact, mothers often pride themselves on the fact, as it is universally considered by them as a sign of good health; it is usually due to overfeeding, and should always be corrected; there is no such condition as "healthy vomiting."

Vomiting has already been considered; it may be due to overfeeding, underfeeding, too high fat in the milk, irregular feeding, milk unsuitable for the infant, too much air swallowed, neuropathic child, pyloric stenosis, etc.; the treatment depends on the cause.

Loose stools (watery, green, and poor in substance), passed several times during the day, may take the place of the normal formed yellow homogeneous stool of healthy infants; these stools are most often seen in the first few months; they are at times present in infants who show no other signs of ill health; these stools are usually due to irritable intestines and increased peristalsis. The stools in infants with exudative diathesis and in cases where the milk is unsuitable for the infant have already been considered. The stools in the exudative diathesis are frequent, contain mucus, and may contain pus, blood, and eosenophile leucocytes. In dyspepsia they resemble those of artificially fed infants fed on mixtures high in fat and sugar and low in salts and proteins. The stools often vary in consistence, owing to the varying composition of breast milk.

Anorexia is one of the first and one of the most important symptoms of impending digestive disturbance; it is a warning sign of overfeeding; it is obstinate after infections, and is persistent in neuropathic infants and in infants with exudative diathesis.

Constipation in breast-fed babies is as frequently met with as in artificially fed babies. When there are no general symptoms present, this symptom requires no treatment. It may be due to faulty innervation of the rectum and anus; in these cases passing the little finger into the rectum often produces a movement; at times it is due to insufficient residue or insufficient food; the carbohydrates have the greatest effect on the bowels; no infant is too young for fruit juices if it will take them; drugs by mouth should be the last resort, and only used when urgent; suppositories and enemata are better but should not be used too frequently. The best suppositories to use are those containing glycerine; enemata should be made of soap suds or sweet oil if the fecal matter tends to be very hard. In certain cases where the constipation is due to insufficient response of the sphincter, the sphincter may be trained to response more quickly by passing graduated glass or wooden bougies; this should be repeated twice daily. In cases associated with colic, ℥i milk of magnesia can be given in a little water.

A NEW TEST FOR INCIPIENT CANCER OF THE BREAST.*

By G. BETTON MASSEY, M.D.,

PHILADELPHIA.

The problem involved in the diagnosis of early carcinoma of the breast usually presents itself in a comparatively young woman during the years of functional activity of the gland. The position of the medical adviser who dreads unnecessary mutilation, as we all dread it, whether the patient be a near relative, a member of a family long depending on us for advice, or merely a stranger applying for our best service, is a delicate one when the adviser is also keenly aware of his stern duty to destroy all cancers in their incipient stage or stand a slacker, with the ultimate death of the patient on his conscience. A hard professionalism acquired in the school of surgical experience will demand that all mammary tumors be operated on at once. Yet a policy of "wait and see" is a strong temptation to many.

A small proportion of mammary tumors in younger women are not cancerous. A larger proportion are malignant, and curable in this stage by prompt measures of a most definite character. On a correct diagnosis may depend the saving of womanly symmetry on the one hand and of life on the other.

To cut into such a tumor for a specimen for microscopic examination, even if a negative report would be conclusive, which it rarely is, would be malpractice. The course of the Health Officer of

*Read before the American Electrotherapeutic Association at Atlantic City, Sept. 11, 1917.

New York City last winter in inviting physicians of that city to increase the rate of growth and precipitate metastases in their patients by such biopsies should have received greater rebuke than it did in the editorial columns of the MEDICAL RECORD. The incomplete knife operation, with frozen section examination during the operation, is most unreliable, the negative evidence of malignancy being uncertain and of little value. Besides, a mutilating operation is not avoided in benign cases.

The test of these clinically uncertain breast tumors to be described in this paper is curative rather than harmful to many varieties of benign growths, and since it postpones destructive eradication of those that are positive to it, or probably malignant, for periods of but two to six weeks, and is in no particular an irritant, it causes but little delay in those that demand radical treatment.

Such clinically evident carcinomas of the breast as those that are ulcerated, adherent to the integument, that present a retracted or galactorrheal nipple or enlarged glands in the axilla, need no test of any kind. The lay diagnosis is often correct. Not an unnecessary day should be allowed to pass without their being placed under effective treatment, together with enlarged regional glands, whether this treatment be destructive ionization, if the method is available, or the knife; or if the case is not suitable for radical treatment no time should be lost in beginning a course of intensive radiation.

Turning to the group of incipient mammary tumors that do not present the clinically conclusive evidences mentioned, we should note particularly that *tenderness* and *aching sensations* are *not* among the symptoms of a frankly malignant growth in any stage. Pain is, of course, present in the late stages, usually of a lancinating character; but someone has aptly said that pain is not a sign of cancer, but is a sign that a patient is dying of cancer. It is rarely present in the early stage. The uncomplicated cancer of the breast, of whatever variety, usually steals on the victim without sensory symptoms of any kind, and may give rise to extensive internal colonization before accidental discovery. Fibromas are also usually without sensation.

Nevertheless, a tender lump in the breast, or one that gives rise to a stinging sensation, may be carcinoma associated with other morbid conditions. Tenderness may indicate a chronic mastitis masking a beginning adenocarcinoma. It also accompanies cystoma of the breast, single or multiple. though these cysts have frequently been found to be the site of carcinomatous nodules on their inner walls.

The rationale of the test to be described is the removal by an effective method of the chronic mastitis that causes or complicates the hardened, tender spot in the breast, and thus either remove the tumor, together with all tenderness, or else remove the complicating mastitis and leave the hard, nontender tumor as a clinically evident carcinoma, cyst or fibroma—in either case now demanding destructive removal without delay.

The test is the application to the tumor of the faradic current from the long secondary wire of a well-built machine, the application to be of twenty minutes duration with most of the coil in use, the active electrode being a well-moistened pad the size of the tumor placed on the skin over it and held in place by adhesive strips, and the dispersing electrode, a large pad, beneath the back, the patient being in the recumbent position. The application should be repeated daily for two weeks. If the sensory symptoms are then relieved without decrease in the size of the tumor or its disappearance, a positive diagnosis of malignancy may be tentatively made, though a further persistence of four weeks of the applications may be indulged in before operation. If the case be one of mastitis alone there will rarely be any mass left after the second to the fourth week.

Should one's modern equipment not include a faradic coil with a 3,000 to 4,500 feet secondary, a very gentle static wave current may be used, for the indication is for painless, rapidly successive inductions, however produced, though my own experience has been limited to this "high tension" faradic current and the latter is probably preferable. The current of the most recent Morse machine with a slow surge might also be effective.

As to the method of radical operation in a positive case, I urge bipolar ionic destruction, particularly when but a small part of the breast is involved. Eradication of a small carcinoma from the breast without destruction of the whole organ is possible by this method, the patient retaining most of her breast and all of her pectoral muscles. But the axilla should be most carefully explored by touch and any palpable glands destroyed at the same time. Should enlarged glands be found above the clavicle the screened *x*-ray should be employed with thoroughness and with much hope of control or eradication of the disease in this situation.

Finally, I must insist that loss of time in the treatment of an operable carcinoma of the breast, save the two to six weeks specified, is no part of the test or the treatment in positive cases, and that the institution of immediate effective treatment is imperative should the test be positive. The faradic current is advised as a test of malignancy, not a treatment. The electricity in the ionization operation is an entirely different proposition, the high temperature and intense chemical activities devitalizing the malignant tissue in twenty to thirty minutes. A degree of heat or chemical activity short of this destructive effect can only be of harm in cancer, and it is for this reason that high frequency or ordinary galvanic currents as well as applications of iodine, etc., are detrimental, while the decongestive action of the faradic current on nonmalignant vascular stasis and its total absence of effect on the cancer tissue make it valuable in a differential test.

1823 WALLACE STREET.

Sudden vs. Protracted Effort.—Amar states that in "brusque" exertion the intrathoracic pressure becomes from 200 to 300 kilos and the volume of pent-up air 3 liters. The time interval of brusque exertion is two or three seconds, and the above status results from arrest of inspiration. It is therefore not wise to allow wounded men to take part in any intensive form of arm exercises. They should not exceed in any case 20 kilos of action during one to two seconds of time.—*La Presse Médicale.*

THE SIGNIFICANCE OF PYREXIA IN INFANTS.*

By W. W. HARPER, M.D.,

SELMA, ALA.

THE essayist has endeavored to make this paper strictly practical and has therefore excised all extraneous matter. He wishes to paint the picture of his daily rounds. Frequently the doctor is called because the mother finds that the baby has fever—the pyrexia often being the only symptom. As the mother demands to know the cause of the fever, the doctor will do well to keep in mind the more common causes. These are: Acute tonsillitis; acute otitis media; pneumonia; acute gastrointestinal indigestion; the exanthemata (*a*) measles, (*b*) scarlet fever; osteomyelitis; rheumatic fever; malaria; typhoid fever; pyelitis.

Acute Tonsillitis.—If the doctor makes it a golden rule to examine the throat of every child, even if the child is brought to his office for a finger scratch, he will be abundantly rewarded. Frequently he will be surprised at his findings, and he will never be embarrassed by the other doctor finding a throat lesion which he failed to detect because he did not look into the child's mouth. Follicular tonsillitis gives a high temperature and one look is sufficient to make the diagnosis.

Acute Otitis Media.—A child that is crying constantly is either hungry or has earache. If the crying is from hunger the child will become quiet when fed, but if due to earache the baby will either refuse to nurse or will turn away from the nipple and scream with pain. Otitis media usually causes high temperature and intense earache, but not infrequently the baby gives no evidence of pain; therefore a careful ear examination should be the routine. As long as one can see the cone of light and the ossicles, one may be sure that there is no pus in the middle ear. A red drum indicates an inflammation, but it should always be borne in mind that rough use of the ear speculum or an attempt to wipe away wax with a cotton applicator very quickly reddens the drum of a baby's ear, therefore handle the speculum gently and try to see the drum by "looking by" the wax.

Pneumonia.—When called to see a child with a temperature of 103° or 104°, which persists for twenty-four hours, after thorough purgation, one should suspect pneumonia. For the first twenty-four hours the physical signs are usually negative. In fact, an infant may go through an attack of pneumonia without a single physical sign. If, however, *light percussion* is done over the entire chest, one may detect a small area of dullness at an apex or along the outer fringe of the lung. In the absence of physical signs, a continuous high temperature, rapid respiration, a "dopy" appearance of the patient, and a marked leucocytosis should warrant a diagnosis of pneumonia. It must be remembered that in pernicious pneumonia the system may be so overwhelmed with toxins that the leucocyte factory fails to respond to the toxin stimulus—in which case there will be no leucocytosis, but a differential count will show a high percentage of neutrophiles.

Acute Gastrointestinal Indigestion.—With the hyperpyrexia there is a history of a dietetic error. The vomitus contains sour, undigested food. The symptoms promptly subside after a dose of castor oil and a water diet for twelve hours.

Measles.—Usually there is a history of an epidemic. Kopliks spots appear early, the conjunctivæ are injected and there are evidences of a coryza. A dirty, crescentic eruption shows on the face about the fourth day, and rapidly spreads over the body.

Scarlet Fever.—Scarlet fever is ushered in with fever, vomiting, marked angina of throat and enlarged tongue papillæ—the "raspberry tongue."

Osteomyelitis.—No examination of a child is complete until the bones and joints have been carefully manipulated. If, in a case of hyperpyrexia one detects a tender, diffuse edema over a long bone which is painful when handled, and if the child positively refuses to use the part the diagnosis of osteomyelitis is justifiable—if there is a leucocytosis.

Rheumatic Fever.—It should be remembered that under three years of age rheumatism is not common. Joint infection in infancy is usually an epiphysitis—due to the staphylococcus or *Micrococcus catarrhalis*. Non-traumatic epiphysitis under six months is always syphilitic. Rheumatism when it affects a child, as a rule does not involve the joint but produces an endocarditis, pericarditis, or carditis. A child that is sweating in the presence of hyperpyrexia is probably suffering from a rheumatic infection.

Malaria.—Infants do not have chills, but the cold stage of malaria is ushered in with pallor or cyanosis. In acute malarial fever there is no enlargement of the spleen. Although running a very high temperature these little patients do not seem to be very sick. If a blood examination fails to show plasmodia, it will usually reveal a decrease in red and white cells, an increase in percentage of endothelials, stippled red cells, anisocytosis, and polychromatophilia.

Typhoid Fever.—Typhoid fever is much more common among infants than is supposed. The child is not pale, but has a rather suffused appearance, soon grows stupid, the tongue has red edges, and soon becomes dry, the spleen enlarges and feels soft to the touch, the pulse is slow, and there is a stair-step rise of temperature. Blood examination shows a leucopenia with absence of eosinophiles. A blood culture in the first few days will show typhoid organisms. In the absence of an incubator and ox-bile culture media, one may use sterile physiological salt solution—twenty to thirty drops of blood to several c.c. of solution, and place the tube in the pajama pocket during the night and the inside coat pocket during the day. Twelve to twenty-four hours at body heat should show motile organisms under the microscope, which, when stained by Gram's method would show typhoid bacilli. Widal test should be positive after the eighth day.

Pyelitis.—In every irregular fever always suspect pyelitis—especially in girls. The leucocyte count is high and a differential shows an increase of neutrophiles. If the patient is a girl, secure a specimen of urine by holding her over a vessel while she nurses, or by catheter; if a boy, apply a finger cot or rubber bag over the penis. Do not use cotton as this strains out all pus corpuscles. In pyelitis

*Read at a meeting of the Chattahoochee Valley Medical and Surgical Association, held at Warm Springs, Ga., July 10-12, 1917.

the urine appears milky macroscopically—which milky appearance does not disappear on addition of acetic acid and heat. Such urine under the microscope shows pus cells and bacteria.

ADVANCEMENT IN OBSTETRICS.*

By MARION T. BENSON, M.D.,

ATLANTA, GA.

Last to share in the advance of modern medical science has been obstetrics. According to a statement made by H. Crutcher obstetrics is not among the respectable arts, and never will rank as a respectable art until it is made respectable. The profession is to blame for the abuses in obstetrical practice and until the profession takes the steps to elevate obstetrics to the high plane which it so richly deserves, human life will be sacrificed.

According to E. T. Davis "modern obstetric surgery has been slow in developing because human life has been cheap. Compensation is given willingly for the removal of abdominal tumors with a reasonable certainty that they would not return, but the birth of a child is the beginning of trouble and expense for a considerable period of years and the legal value of human life is its wage-earning capacity." He further illustrates this in the experience of a young general practitioner, who had been trained in the modern antisepsis. He was called to attend the patient in her home and made every effort to secure proper aseptic technique. The husband interrupted him in this, saying that it was an ordinary case of confinement and that he could not afford to have all this done for his wife.

According to DeLee "there die annually in the United States 20,000 mothers from childbirth, besides the mortality of the newborn, which is also very high." This enormous waste of human life, has created a new interest in obstetrics, and the time is ripe for a continued advance in this branch of medicine, and it is time for obstetrician and gynecologist to write, think, and talk the advancement of obstetrical practice.

In the last few years, I am glad to state, the science of obstetrics has advanced and this important field of practice will continue to advance as the laity themselves have become aroused and are demanding more than a midwife.

The two most recent agitations in obstetrical work are the so-called "twilight sleep" and "pituitrin." In regard to "twilight sleep," which has been heralded from one end of the country to the other, not only in medical journals but in the lay press, the consensus of opinion is that scopolamine is a dangerous drug and should not be used in obstetrical practice. During the first stage of labor, we have other drugs, which if administered properly and carefully, will give an analgesic effect without harm either to mother or child. These drugs are morphine and chloral. These drugs given during the first stage of labor will aid dilatation, relieve muscular spasm, and diminish shock. Morphine can be given in small doses hypodermically during this stage, and as stated above, will not harm mother or child. Chloral has to be given by stomach and is very likely to be rejected, therefore, if it is rejected, morphine can be used. In the second stage morphine and scopolamine have a very injurious effect as they prolong this stage of labor, subjecting the child to a longer period of pounding and uterine compression and the longer the second stage of labor is allowed to continue the longer we have interference with fetoplacental circulation.

In the second stage, we have gas-oxygen, ether, or chloroform, and when we consider the life of the infant, as well as the after effects to the mother, we should be very particular in the use of any drug which will affect either. With either of these, we control the second stage of labor and one or the other should be used accordingly.

The use of pituitary extract has been under discussion quite extensively and most writers on this subject condemn or limit its use. The danger is rupture of the uterus or its effect upon the child. I have to differ from the majority of obstetricians in regard to the use of pituitrin. In my own private practice I have used it in some five hundred cases and have yet to see any injurious effects either to the mother or child. We should know when to give it and when not to give it. We should also know how much to give at a dose and what we may expect from the same. Pituitrin should never be given until the cervix is fully dilated, the head presenting in the pelvis, or just above the ischial spines or on the pelvic floor. We must be sure the outlet diameters are ample to allow the exit of the head, and when it is used under the above conditions, I have yet to see any injury to either the mother or child. I have used it before the cervix was fully dilated, and if this is done one is very likely to have a torn cervix, so therefore do not use it until there is a fully dilated cervix. In inertia uteri it has a most marked effect. In those cases in the past, where there has been a fully dilated cervix with no pains, one has been afraid to leave his patient, and sat around all day or all night with the family and patient, but now an injection of pituitrin not only relieves the patient of the nervous dread of her approaching confinement, but will also relieve the physician of a very long wait.

In abruptioplacentæ, when the head is engaged, after the rupture of the membranes, small doses may contract the uterus on the fetal mass sufficiently to check hemorrhage from the placental site.

In the third stage, after the delivery of the placenta, pituitrin has a marked contracting effect on the uterus and the so-called after pains are very markedly diminished and may be even eliminated entirely. I have noticed particularly in multiparæ, who have suffered in previous confinements with the after pains, that there has been marked difference when pituitrin extract has been used.

In cesarean section, just as the incision is made in the uterus, an ampoule of pituitrin will minimize the amount of hemorrhage. It should not be given before the operation is begun because the uterine spasm may be so great as to interfere with proper suturing.

If the uterine contraction is too great, or if we find the delivery of the child is too rapid, it can be checked or retarded according to the operator's desire by either increasing or diminishing the use of chloroform. In some cases where I find a delivery

*Read at the annual meeting of the Chattahoochee Valley Medical and Surgical Association, held at Warm Springs, Ga., July 10-12, 1917.

is too fast, by pushing the chloroform I have been able to retard same, and then letting the patient come out from under the effects of the chloroform, making the delivery as slow as I desire.

The dose of pituitary extract should vary according to the desired effect, from ¼ to 1 c.c. This can be repeated in 30 to 60 minutes.

Another advance in obstetrics is in asepsis and antisepsis. They should be practised most carefully in every case of obstetrics. If the obstetrician is careful and if he is clean at the time of the delivery, and if the patient and nurse are clean, there is absolutely no reason for infection afterwards, and the time is coming when infection in this line of work will be unknown. In my own work of something over five hundred cases delivered in the last seven years, I have not had a single case of infection and this work has been carried on among the poor, as well as the well-to-do, in homes and hospitals. It shows that if we use ordinary precaution peritonitis from childbirth will be unknown.

Every case of lacerated perineum either of the first, second, or third degree should be repaired as soon as possible after delivery. If this is done, it will save many a woman future trouble. We should see that the smallest tear is repaired, and by so doing we can often save the muscles, which have been separated through the stretching and thereby help to keep down the old familiar saying that we so often hear when a patient walks into our office, "Doctor, I have never been well since my baby was born."

It will also help to keep down infection, if the repair is done immediately, as we shall then not have a gaping wound, allowing infection to pass through. As stated above, in my work, I have not had a failure of closure or infection in the past seven years.

Cesarean section is being done more frequently now than ever before and with less danger to mother and child. In some parts of the country there are too many cesareans being done and in some parts too few as a life saver.

The development of modern obstetrical surgery dates from the time when Saenger accurately closed the uterine muscles and peritoneal covering separately. The mortality of the classic section immediately fell to the rate corresponding to that of other abdominal operations.

Where we have a deformed pelvis, or where a quick delivery is required, as in eclampsia, cesarean section is indicated, and if properly carried out, will give a beautiful result.

The use of forceps has been handed down to us from the days of Aetius. The instruments which he used were two crochets. From this time on there has been a gradual development up to the modern obstetrical forceps. Aetius recommends in difficult labor—first the use of the fillet; if that fails the forceps; and then, if still unable to deliver, perforation.

As we learn from books of the Eleventh and Twelfth centuries the Arabian physicians used forceps and were skilled in their application. They possessed two varieties—straight and curved. So we therefore see that the forceps has been in use ever since there have been any writings upon obstetrics. The forceps should never be used until the head has become engaged in the pelvis. The old method of high delivery should be a thing of the past, on account of the danger of injury to the mother or child, a danger which is very great unless the forceps is applied very skillfully. In applying the forceps we must remember that permanent injury can be caused to the child, even when not destroying its life, by leaving scars or depressions which would develop in later life. I know it is the practice of some obstetricians to deliver the majority of cases with the forceps. They are in a hurry to get through, or they do not care to wait, so they apply the forceps and make quick delivery, lacerating cervix, perineum, etc., thereby causing permanent injury to the mother. We must remember that two lives are involved, and in no line of work are judgment and skill more indicated than in obstetrics.

To minimize shock and pain, the injection of novocaine or cocaine into the perineum, according to the method of Crile, is advocated. I have had very little experience with this in my work and simply mention it as one of the recent measures which have been brought out.

Rectal examination is advised very strongly by some obstetricians, who claim that they seldom make a vaginal examination. The object of the rectal examination is to keep down infection, but I fully believe that if our hands are not infected before we make the examination there will not be any infection. However, when there is any risk of our hands being infected, I would recommend the rectal examination.

J. C. Hirst and S. T. Barnett have both recently recommended the use of corpus luteum by hypodermic injection for nausea in pregnancy. This very troublesome part of obstetrical work in the early stages is so greatly relieved, according to their reports, that it seems worth recommending. I have used it in a limited number of cases and the results have been very gratifying.

In conclusion let me warn every one, either man or woman, that unless fully prepared to give the time and skillful knowledge, he or she has no right to accept the care of an obstetrical case. Unless one is able to perform a vaginal or abdominal cesarean section; to operate where there is ectopic gestation in any form, or to open the abdomen promptly and repair rupture of the uterus, and in fact unless he understands obstetrics thoroughly, he should not practise obstetrics.

Every one practising obstetrics should be perfectly familiar with the mechanism of labor and of the various presentations, should know when to wait and when to hurry, when to use and when not to use forceps, should be able to do promptly primary perineorrhaphy, how to prevent and arrest postpartum hemorrhage, and should be familiar with asepsis and antisepsis. When these requirements are met we shall have a better understanding of obstetrical work and obstetrics will be advanced and many lives will be saved.

Holland Society of Psychoanalysis.—This society was organized in February of this year in affiliation with the International Society for Psychoanalysis. — *Nederlansch Tijdschrift voor Geneeskunde.*

A FURTHER CONTRIBUTION RELATIVE TO CAPILLARY CALIBER AND ITS RELATION TO NORMAL AND DISEASED STATES.

By W. V. GAGE, M.D.,

WORLAND, WYO.

SINCE the publication, in the MEDICAL RECORD of Sept. 1, 1917, of an article entitled "The Relation of Capillary Caliber to Normal and Pathological Sensation and Function," many new phases of the subject have presented themselves, and I wish, in the following paper, to continue a consideration of what, to me, seem to be facts bearing out the statements of the previous article.

The enormous potency of the hitherto overlooked element of capillary caliber, as the real factor which determines between health and disease, is being hourly more impressed upon me, and I have already, in my own mind, classified as "facts," manifestations which I formerly tabulated as "theories," and I hereby wish to place myself on record in support of this simplest and, upon analysis, most obvious physiological and pathological principle, i. e., "Capillary caliber is back of every function and sensation, both physiological and pathological, experienced by the economy."

I realize that I am asking much of my readers when I suggest that they accept as facts the statements I make in this and the previous paper; but I feel so positive regarding the position I take, and so sure as to the ultimate outcome of the matter, that I base my all upon the statements made. By this I mean upon the fundamental principle involved, as the newness of the idea necessarily demands faulty premises on my part, and possibly "proofs" which time may show to be fallacious.

I believe that this single factor of capillary caliber determines an individual's energy or lassitude, his chill or fever, his health or sickness, his sexual life, his birth, maintenance, decline, old age, and death.

As the element which *compels* old age, the contracted capillary stands alone, whether this old age, in organ or individual, has back of it accumulated years, or faulty, hurried living, and the gray hair or baldness, the atrophic, glossy skin, the tooth loss and absorption of the alveolar processes, the loss of body heat and weight, the dimness of vision and the defective hearing, the pacific mentality and blunted sensation reactions to all outside stimuli, such as fear, anger, joy, or pain, all point to lessened capillary caliber.

In the tissue changes of old age which spell disease, as in malignant growths, etc., we must look for the dilated capillary, but we must recognize that dilatation is comparative only, *i.e.* a caliber looked upon as pathological in the aged might be normal in youth, the age of the elastic capillary.

The contracted capillary is the "shepherd of old age," and by it old age is not only produced but protected, for it throws a fostering arm around the declining years of life by obtunding all of the functions of youth which spell stress and strain and resistance.

The age-contracted capillary promulgates a mental and bodily aquiescence, a pacific state which renders age immune to the worry and care and anxiety of former years.

In contradistinction to the quietude of old age, with its contracted capillary, consider the brutishness and cowardice and bluster and great susceptibility to pain in the ordinary drunkard, whose "trade mark" from nose to stomach, and from bleary eye to bloated extremities, is the dilated capillary. The dilated capillary spells pain and over-functioning. The contracted capillary stands for anesthesia and lessened functional activity.

Can it be possible that we shall at some future time be so able to regulate blood supply that we may command a return to normal, in a given diseased organ, or stay the hand of time in the bringing about of early old age?

The tortuous artery of old age is the natural consequence of distal capillary contraction, and no other abnormality could be rationally looked for, unless we theorize as to the possibility of arterial dilatation, to take the place of the tortuosity, and dilatation is prevented by the sclerosis which has come to be looked upon as a classical finding in the old age artery.

The familiar pride-purchased, agonizing pain due to the wearing of a tightly fitting shoe is only equalled in exquisiteness by the relief which comes when the shoe is removed and the foot allowed to assume its normal condition.

The throbbing pain from the tight shoe, because of its grossness, has never been considered worthy of investigation, but it is due to an enormous interarterial pressure, acting against an artificial obstruction—the inelastic leather casing.

The interarterial pressure, which I speak of as "enormous," can be appreciated best after the following experiment: Suppose you find a blood presure of 140 in a given case. You have inflated your arm-band, until the pulse is no longer heard, and the gauge marks 140. Take this same arm-band and fold it upon itself, to about the size of the hand, place it upon a flat surface, and press upon it with the hand, and again inflate until the gauge shows 140. You will probably be astonished to note the amount of pressure needed to hold the index of the gauge to the selected reading.

Imagine, with a pressure like this, the contest going on in a foot imprisoned in a tight shoe when the blood pressure tries to overcome the binding force of the inelastic leather constrictor.

The phenomenon of the tight shoe pain, and the inflammation and tenderness and swelling which follow, explains all the pain phenomena to which the economy is subject.

Thousands of physiological and pathological problems will be solved, when once we start to ignore the nerve, except as a carrier of sensation or stimuli, and place the blood-vessel where it belongs, as the factor back of the sensation transmitted. One will surely find that the intensity of pain is in a direct ratio with the lack of elasticity in the tissues which go to make up the part affected.

As to the dilated lung capillary, and its role in the production of dyspnea and air hunger, I refer the reader to my former paper, but will further add that, to me, the lung is analogous to a "carburetor," and that the caliber of the lung capillary determines as to whether or not the economy is

asked to "run on a mixture either too rich or too thin," *i.e.* the dilated capillary and consequent compressed aid cell, meaning too rich a mixture, or the contracted capillary and dilated air cell which mean too thin a mixture, or air in excess of the carrying power of the contracted blood vessel.*

Please note that the so-called incurable diseases, either medical or surgical, have with them either the *chronically contracted* or *chronically dilated capillary*, while in conditions which we look upon as amenable to treatment, we find an *acute* departure from normal capillary caliber.

This list includes all diseased states, from tonsillitis to cancer, and from a pimple to acute and chronic albuminuria; and the acute condition, in any diseased state, becomes the chronic one so soon as overstrain or hardening causes the capillary to lose its resiliency.

We must look back of the vasomotor system for an explanation of the variations in capillary caliber, either transient or permanent. We must see the vasomotor system simply as a transmitter of stimuli.

It is the hormones, elaborated by the ductless glands, which determine as to normal or eccentric bodily states, and these ductless glands deliver to the economy a complex chemical substance which is normal or abnormal according as to whether or no the gland is supplied with blood through the medium of a normal or abnormal capillary.

This fact should be kept in mind in the consideration of the action and interaction of the ductless glands. A perfectly healthy ductless gland with a normal blood supply may be delivering an abnormal hormone, because of the fact that it is being asked to metabolize a chemically lacking hormone, furnished by a faulty ductless gland on which it is dependent.

Is the suprarenal the principal gland in the production of the hormones which stimulate capillary contraction? If so, let us find the gland which must surely be working in opposition to the adrenal, learn the control of both glands, and we shall have gone far toward the handling of the bodily functions.

One element must be constantly borne in mind, *viz.*, owing to the fact that the circulating system is a closed tube and of a limited capacity, it must be obvious that capillary dilatation in one organ or part of the economy must of necessity mean compensatory contraction at some other point, and maintenance of balance will compel *two* regions where pathological or at least abnormal functioning may be looked for.

The subject is an endless one. Take under consideration any normal or abnormal function, any physiological or pathological process or result, *and consider the impossibility of producing that process or result without a capillary of the caliber essential to the state in question*, and the vastness of the field is startlingly evident.

I hope that this, and the previous paper, will create enough interest to stimulate others to work along the lines referred to, as I am satisfied that herein lies the solution of many an hitherto unanswered problem.

*The illustration is possibly out of place, but I was at a loss for another so applicable.

Medicolegal Notes.

Damages for Result of Exposure to Cold.—A physician was summoned to attend a patient on a cold night in March. The journey of about fifteen miles was made in a buggy. On returning, at an exposed point on the road he was prevented from crossing railroad tracks by a standing freight train for about fifty minutes. He was in good condition when he stopped, but after about fifteen minutes he discovered that he was beginning to feel numb and chilled. By the time the train moved he had become so affected by cold that he was no longer able to grasp the lines, and was compelled to wrap them around his wrists and arms in order to control his team. As a result of the exposure he contracted articulate rheumatism and suffered from this disease for a long time. In an action against the railroad to recover damages it was held that he was entitled to recover, and judgment for $875 was affirmed.—Cowdrick vs. N. Y. Central R. Co., 65 Pa. Superior Ct. 416.

Privileged Communications.—The South Dakota Code of Procedure, §538, a statute substantially similar to §834 of the New York Code of Criminal Procedure, provides that a physician cannot, without the consent of his patient, be examined in a civil action as to any information acquired in attending the patient necessary to enable him to prescribe. In an action by a nurse against an administrator for services rendered to the decedent and his wife it was held that testimony of a physician as to the general character and value of the services rendered by the plaintiff as a nurse to the patient was not privileged. The plaintiff called as a witness, to prove her services as a nurse and the value thereof, a physician who attended the deceased during his illness and for the same purpose another who attended the deceased's wife during her last illness. The defendant's objections to this testimony on the ground of privileged communications was held properly overruled. The court said that the general policy of such statutes is well understood. It was sufficient to observe that these physicians testified only to the general character and value of the services rendered by the plaintiff as a nurse, and were not examined and did not testify as to any information acquired in attending their patients necessary to enable them to prescribe or act for such patients. A similar decision was arrived at under the New York statute in similar circumstances in re McQueen's Estate, 13 N. Y. Supp. 705, on the ground that the information testified to did not at all enter into the physicians' professional conduct as the physicians of the patient, but related to a wholly distinct and separate subject.—Higgs vs. Bigelow, South Dakota Supreme Court, 164 N. W. 89.

Unrecorded Certificate—Compensation for Services.—Action was brought upon a promissory note given by the defendant to a firm of physicians for services rendered in treatment by a system known as "Chiropractics." The defense interposed was that such services were rendered by the payees of the note in violation of the Alabama criminal statutes prohibiting the practice of medicine by anyone who has not obtained a certificate of qualification from the board of medical examiners. The Alabama Court of Appeals holds that the statutory provisions found in chapter 39 of the Alabama Code, embracing §§1626-1646, relative to the right of physicians to practise medicine without certificates of qualification are regulations for the benefit of the public as well as for persons dealing with those who hold themselves out to the public as professionally qualified to treat diseases of human beings; and it is the public policy of the State to punish the violations of these statutes, and contracts made in violation of these statutes are void in the hands of all persons involved in the guilt of the transaction. Contracts made in violation of these provisions are void in the hands of all persons involved in the guilt of the transaction. Any contract made in violation of Code 1907, §1644, providing that a physician shall not be entitled to compensation for services where his certificate has not been recorded, and §7564, providing a penalty for practising medicine without a license, is void *ab initio;* hence it is a good defense to a note given for the services of a physician that the physician is acting in violation of such sections.—Whitehead vs. Coker (Ala.), 76 So. 484.

Military Medicine.

TUBERCULOSIS IN THE FRENCH ARMY.

WHILE tuberculosis in the French Army is a sufficiently serious problem, an analysis of individual reports readily shows that there is much misconception in this regard. Tuberculosis is a civil plague, and in fact was such long before the war, but it has never seemed reasonable or plausible that the picked fighting men could be stricken wholesale with active tuberculosis. A study of several articles, abstracts of which have been published in the MEDICAL RECORD, show plainly that only a relatively small fraction of the so-called tuberculous soldiers have, or have had, active tuberculosis. The vast majority present the disease in the latent or stationary form, or else have only adhesions from past pleurisy of presumably tuberculous nature. In one material instance, at least 50 per cent. of the alleged "tuberculous" soldiers were doing full duty at the front. It is, of course, true that on a peace footing none of these 50 per cent. would be in the ranks.

But the 50 per cent. or less who have been invalided naturally make up a great body of men who require hospital treatment, and the real problem consists in finding accommodations for them. This is discussed by Leuret in the *Journal de Médecine de Bordeaux* for July. In the absence of exact data we can only infer that this problem deals essentially with the salvage of lives both for military duty and on general principles. The selection should be along the lines which obtain in sanatorium practice, *i.e.* the incurable patient constitutes a separate problem. In Leuret's article, special sanatoria, wards in general sanatoria, and out-of-door clinics, are all discussed. It is the consensus that 300 beds should be the maximum for a single service.

The movement extends beyond the confines of the actual fighting men, for sanatoria in industrial districts seem to provide hospitalization for the workmen as well, although it is not clear as to whether there is segregation of one or the other class. But these sanatoria for workingmen appear to be under the control of army physicians. The tuberculous soldier who may be regarded as on the road to recovery does light farm labor, which favors the cure, and at the same time makes him useful to his country. Dr. Cantonnet is an enthusiast regarding the "work cure." Other light occupations in the country are also facilitated, so that open-air convalescence is rendered possible for men who take their families with them from the cities.

Some Experiences in the German Red Cross.—In the spring of 1914, after a five years' residence in Germany, Clarence A. Neymann states that he passed his State examinations in Heidelberg, and had just entered the department of hygiene with the intention of doing some serological work when the war began. In the general excitement that preceded the outbreak of hostilities he was prevailed upon to join the Red Cross and remained with that organization until the end of April, 1915.

Having only his memory upon which to rely, it is with some hesitation that he offers his impressions of this nine months' service, but he considers that the changes made in the medical organization in Germany since he left two years ago are of minor importance.

At the outbreak of the war the military hospital service was divided into dressing stations, field hospitals, base hospitals and evacuation hospitals. The dressing stations were situated behind the firing line, but within artillery range. The field hospitals were out of range of all but the heaviest artillery and were movable. The base hospitals were far inland, entirely removed from the scene of action, and the evacuation hospitals were in the vicinity of the base hospitals. The evacuation hospitals were really mere homes for convalescents, usually presided over by an elderly physician of the town or village in which they were situated and supervised by the nearest base hospital. This was the sum total of provision made for the sick and the wounded at the outbreak of the war. There were insufficient facilities for returning the men from the front, most of the wounded arriving at the base hospitals in cattle cars on straw bedding with wounds exposed and fractures often without splints.

Germany was sure of a victory within three months and as a consequence no provision had been made for specialized treatment of any kind. The situation in Heidelberg, where he was stationed, as in other university towns, was a little better than elsewhere because of the university clinics already in existence, and these clinics, having become base hospitals, naturally cooperated in exchanging their sick and wounded.

During the first part of the war, that is, up to the time of the battle of the Marne, not a single mental case appeared in the hospital, the "Vereinslazaret Stadthalle," a base hospital of 280 beds with a very active service, where Neymann was stationed. The psychiatric clinic in Heidelberg was half filled with ordinary wounded and there seemed to be no need of a psychiatrist anywhere. Neymann considers that this was partly due to the attitude of the troops, who were buoyantly sure of speedy victory, and partly to the fact that, owing to the general unsatisfactory conditions as already outlined, no attention was paid to individuals who acted queerly. Thus psychoneuroses hardly existed and patients suffering from deeper-seated mental disorders were swept along by the multitude.

Later, with the definite departure from open to trench warfare, Neymann states that the picture changed. Hardly a transport of sick and wounded, arriving twice a week, but what contained its quota of mental cases. The psychiatric clinic had assumed enormous proportions and had become so overcrowded that the psychoneurotics had to be treated in the base hospitals. Now these psychoneurotics slowly but surely began to be a nuisance in the base hospitals that did not have a psychiatrist attached to them by accident. They were "uninteresting cases" to the men of eminently surgical training and were sent to the evacuation hospitals, stagnated there, and finally returned to the front. There all their former symptoms reappeared immediately and they were sent back to the base hospitals. Neymann speaks of one case that went through this procedure three times.

Finally the government stepped in and provided each base hospital with a psychiatrist from a psy-

chiatric clinic, provided one was near at hand, as was the case in Heidelberg. The psychiatrist also dealt with the case of plain slackers. Besides this, the government sent a proclamation to all base hospitals, warning against returning psychoneurotic patients to the front as *felddienstfähig*, capable of service in the field in a haphazard way. Conditions thus were bettered. Patients were kept in the base hospitals until improved, then sent home for a rest and finally assigned to garrison duty, near their home towns. The plain slackers were assigned to heavy labor away from home, while cases of dementia precox, general paresis, etc., were declared unfit for duty and concentrated in the regular state institutions. They were, however, treated as soldiers and enjoyed especial privileges whenever possible.

Neymann describes four types of psychoneurotics which he encountered in the base hospitals. It was for the interest of all concerned to remove severer affections to the psychiatric clinics as soon as possible, even if they were severely wounded. This was done in part directly from the field hospitals and was the only classification these hospitals attempted, all other sorting being done by the base hospitals where there was time and for a more thorough examination.

The first type of psychoneurosis which Neymann brings before us and which he states stands out before all others is that of grenade fever. These individuals were usually stoop-shouldered and narrow-chested, with a poor physical build and a naturally weak constitution. All complained of indigestion (the hospital served good but coarse food), backaches and headaches. However, they lived through the hospital routine pretty well and only lost control when grenades were mentioned or experiences at the front were dwelt upon. Then they would lose control so far as to fall down to the ground. They would be pale, restless, and nervous and could not sleep without hypnotics for a number of days. Unfortunately no association tests were done.

The second class was represented by those individuals who had had especially trying experiences and then simulated some internal or mental disorder for which men in their company had been sent to the rear. This condition would persist for months, even after they were told that they were unfit for duty in the field. Pseudo-epilepsy was one of the forms simulated. One case of this type had been struck between the shoulders by a mine which did not explode just a few days after a man in his company had been sent to the rear on account of repeated attacks of epilepsy.

From this to slackerdom is but a step and all intermediate stages were encountered. All such individuals were considered unfit for duty at the front as they lowered the morale of their entire companies.

Neymann points out that quite opposite from the reaction of the naturally weak and neurotic is that of the mentally slightly deficient. Thus the troops from Bavaria are notably brave, yet among their wounded were many high-grade morons. These individuals, who are wandering laborers, never settle down or get married, spend their money as they earn it, believe in the direct intervention in their behalf of certain sacred statues, can just read and write, and if opportunity is offered will commit petty theft, have not proved bad soldiers.

There were all types of individual reactions. Thus, those patients who had gone through depressions in previous years again became depressed. Hypomanic individuals became very wild and lost almost the last remnants of civilization. Such persons were most difficult to control in the first few weeks after their return from the front, unless they were so seriously wounded that they were confined to their beds. They were constantly exceeding the time limit of their leave, getting drunk and making other kinds of disturbance. After a rest in the hospital for a period of time they usually calmed down again and became manageable. Neymann states that all of these facts agree with our modern psychiatric view of the specific reaction of each individual.—*Mental Hygiene*, July, 1917.

Observations Upon Shock.—In the *Annals of Surgery* for September, 1917. Dr. Edward W. Archibald of Montreal and Capt. W. S. McLean, C.A.M.C., write on shock in war surgery. There are three kinds of service in the surgery of the present war: (1) That of the hospitals close behind the front line, termed casualty clearing stations; (2) that of the base hospitals in France which are usually situated from thirty to sixty miles back; (3) that of the base hospitals in England. In England one sees chronic surgery; at base in France one sees subacute and acute infections, and one goes occasionally shrapnel hunting. But in the casualty clearing station one sees three conditions in particular, which are rarely or never seen at base far back. They are abdominal wounds, the early and severe effects of "gassing" and finally shock; and shock is seen to an extent unparalleled in the experience of any surgeon at home. The very frequency of it was impressive, and not less so the inability of surgeons to rescue such patients when the degree of shock was really serious.

Attention is called particularly to the fact which is not always appreciated that the transport of the wounded from the trench to the casualty clearing station is frequently a most trying experience. The soldier before he is hit is often in a state of fatigue, and not seldom during the winter he is wet and cold into the bargain. Add to this the jolting of a stretcher journey of 1,000 yards down a muddy, slippery, uneven communication trench; add to this the bumping of a horse ambulance along the roads of France such as they are at present well up toward the lines; add to this the transfer to the motor ambulance and a vibratory ride along the stone pavement of that country; add to this a couple of changes of dressing of a painful wound; add a certain loss of blood even in the best cases; add finally the effect of cold, and you get a composite set of circumstances for the reduction of the patient's resistance than which even Dr. Crile could ask nothing better.

A French surgeon, M. Santy, in a very recent number of the *Lyon Chirurgical*, has called particular attention to the influence of great exposure to cold and to fatigue during the time which elapsed from the receipt of soldiers' injuries to

their arrival in hospital. M. Santy had served both in the advanced dressing station and in what corresponds in the French Army to the casualty clearing station, and he says that apart from those who die on the field the occurrence of shock in the wounded soldier when seen soon after infliction of his wound is extremely rare, but that the loss of even a strictly moderate amount of blood, together with the distresses of transport, will frequently push a wounded man, previously in good condition, into what he calls secondary shock, before his arrival at the hospital. There is little need to spend time on the definition of shock. It may, however, be remarked in passing that wounds of the chest and of the head, very rarely indeed presented the symptoms of shock. The authors in going over the notes of their shock cases found that practically all were wounds of the locomotor system or of the abdomen.

From a review of these observations of their bad shock cases the authors picked out a few main facts which they thought merited discussion. As for temperature Guy Kinnaman in an article some years ago pointed out the serious effects of shock upon the temperature. Archibald and McClean found uniformly a serious fall very frequently. If the patients were in marked shock the clinical thermometer would not register, which meant that the temperature was somewhere below 92°. Of 12 cases in which the temperature was low to this extent, death within a few hours took place in 9. If shock were marked, as judged by the general signs, blood pressure was practically always below 75, and occasionally it could not be got at all. Out of seventeen cases with a blood pressure below 75, only three rallied from the shock, and these all died in two or three days from gas gangrene. All the rest died within a few hours after admission or after operation. The pulse was nearly always rapid, 110 or over. This probably has the same significance as in hemorrhage, a lack of sufficient blood to the ventricle in diastole. Respiration was usually increased by 6 to 12 in a minute, *i.e.* 24 to 32, and was always shallow. Hemorrhage, of course, was apt to complicate the situation. It is well known that even a moderate loss of blood tends to predispose to or aggravate shock. However, there was a considerable number of cases in which hemorrhage was either absent or very slight. In these apathy and cyanosis as opposed to restlessness and blanching were marked. Another striking difference lay in the effect of intravenous salt or transfusion, helpful in hemorrhage, useless in severe shock. It was frequently necessary, on account of infection or bleeding, or, in abdominal cases, the presumed danger of peritonitis, to operate soon after admission in the middle of shock. It can easily be imagined how serious such operations were. In a general way, operations aggravated shock very definitely. The old dictum that one should wait for the rally seemed to the writers to be absolutely confirmed by their experience.

With regard to treatment under the existing untoward conditions, a great deal of salt solution was given. It was learned to give it intravenously rather than under the breast; in the latter case it was apt to be absorbed far too slowly to do any good. Rectal salines were often given in addition. Their experience confirmed what all know, that the effect of intravenous salt is very transitory. It rarely held up the blood pressure in serious cases for longer than a couple of hours, often much less. If the trouble were chiefly hemorrhage, results were much better. A number of cases with a blood pressure of 70 or over were saved by intravenous saline. In a certain number they gave, following Hogan, a colloid solution of 25 grammes gelatin in a liter of saline solution. Its effect lasted three or four times longer. Nevertheless, in cases of bad shock it did not avert the fatal outcome. In hemorrhage it was more effectual than saline alone. Transfusion of blood was done in three cases using the citrate method, 16 to 20 ounces being given. Its effect was disappointing; while the color was improved and a slight rise of blood pressure was got, it had no more permanent effect than the gelatin on salt.

Pituitrin was freely used and always brought up the pulse to a certain extent, but this was often transitory, and, on the whole, the authors concluded that it had no real beneficial effect in bad shock. In moderate shock it was of distinct value.

Archibald thinks that shock trouble begins in the vast capillary system, that enormous area of marshy ground in which fluid has such a chance to stagnate. It is known with fair certainty now. from the work of Cotton, Slack, and Lewis, that the capillaries possess active contractability.

Dale and Laidlaw believe that in shock produced by histamin the tone of the capillaries is lost and blood stagnates. For the present, Archibald accepts this as the point of primary failure in traumatic shock. Pallor followed in bad cases by cyanosis was an outsanding feature in the observations of the authors. The veins no longer receive enough blood. If they did, shock could be overcome by gravity and compression, which is not usually the case. Consequently, according to Yandell-Henderson, the failure in the venopressor mechanism is a secondary effect; likewise the gradual failure of the heart and of the coronary supply, all of which assist in the establishment of a vicious circle. The capillary failure leads to insufficient oxidation, which results in asphyxial acidosis. As Henderson says: "The acid substances thus formed cause the protein of the tissue to imbibe water from the blood in much the same manner that fibrin swells in dilute acids. Hence the fatally rapid transudation of fluid from the blood vessels."

Recent English work has demonstrated in shock a serious loss of plasma into the tissues, with consequent rise in the hemoglobin count and the viscosity of the blood in the vessels. All this work suggests, in the opinion of Archibald that hypertonic salt solution at twice decinormal strength would be of some promise. Its chief effect would naturally be to call back into the blood the plasma lost to the tissues. But very possibly it also acts by restoring capillary tone. Archibald has been informed that some encouraging results have recently been obtained at the front with it. He has had no clinical experience, but in one of his ani-

mals, reduced to deep shock by abnormal exposure, the tongue, up to then quite cyanosed, recovered quickly with hypertonic salt a normal pinkish tinge, obviously a local effect on capillaries, inasmuch as blood pressure previously at 35 was raised only to 50.

Regulations Affecting Hospital Care of Soldiers.—While the base hospitals at the Army cantonments are prepared to care for the sick of the divisions, under ordinary circumstances, in case there are an unexpectedly large number needing hospital care the Surgeon General will make arrangements with the civil hospitals for their temporary reception in civil hospitals, and it may become necessary to procure such accommodations for severe cases requiring special apparatus or treatment before time has permitted adequate provision for them in the special Army hospitals. In such cases the Government will pay the usual hospital charges for such patients, but no charges for medical, surgical, or other services connected with them. As the United States Army General Hospital at Fort Bayard has limited accommodations, tuberculous patients may have to be cared for at the base hospitals, but when this is done they will be quartered in wards reserved for them exclusively. Cases of insanity which can be received by their friends upon discharge will be sent home. The insane not thus provided for, if their disability was incurred in the line of duty, will be sent to the Government Hospital for the Insane at Washington, D. C., or to such institutions as the Surgeon General of the Army may indicate. If the disability is not in the line of duty, they will be returned to institutions in their own State, to be cared for by State appropriation.

Hospitals for Our Men in France.—The Army Medical Department announces that its plans for the establishment of hospitals for the American troops in France have been completed. Each unit of 27,000 men will have four field hospitals, two evacuation hospitals, and four base hospitals. The Red Cross announces that when the base hospital units now awaiting call are in service New York City alone will have sent 200 surgeons and physicians and more than 500 trained Red Cross nurses. Four units from this city are already abroad. They are the Presbyterian, Roosevelt, New York Post-Graduate, and the New York Hospital. The remaining units, Bellevue, Mount Sinai, the German Hospital, and Metropolitan units, have long been in readiness for a call to service. There are about 2,000 Red Cross nurses already serving in Europe. Fifteen thousand nurses have been enrolled. It is estimated that this number will be sufficient to care for an army of 1,500,000 men.

Cuban Red Cross Unit for France.—The Cuban Red Cross Society, of which Señora Menocal, wife of the President of Cuba, is chairman, is equipping a 100-bed hospital unit, manned by Cuban physicians and nurses, for service on the front in France. A number of ladies in Havana have set out to raise a fund of $1,000,000 to finance the unit.

A New Portable Hospital.—Experiments are being made, under State auspices, with a new portable hospital devised by Dr. William A. Brooks of Boston, Lieutenant of the State Guard. The new hospital, consisting of four collapsible buildings, is at present located on an elevation near Brookline, Mass. The portable buildings can be taken down, packed, and transported by means of motor trucks in a very short time. The entire outfit is designed with a view to moving it to a scene of emergency in the briefest space of time possible and at the same time providing a complete hospital equipment.

Red Cross Mission to Italy.—The Red Cross is sending a permanent mission to Italy immediately, and announces that it will take every practical step to alleviate suffering and extend such assurance and comfort as is possible to Italian soldiers and the civilian population. Acting on the recommendation of the recently returned American Red Cross mission to Italy, the War Council has appropriated money to develop an ambulance service and to operate such civilian relief as it may be feasible to extend in the immediate future.

German Losses in Three Years of War.—According to declaration made before the German Reichstag by the Independent Socialist, Georg Ledebour, who bases his estimates on the weekly official bulletins issued by Germany up to August 1, 1917, the German losses during the war up to that date are: Dead, 1,132,963; wounded, 2,888,787; crippled and invalided for life, 602,858; prisoners, 602,506. These estimates are even larger than those made by the French and British statisticians.

Ambulance Fund of Poets Grows.—According to the latest reports from the Poets' Committee, the fund which they are collecting for the purchase of ambulances now amounts to $112,457. This fund has already put a number of ambulances to work on the Italian front and by November 15 at least fifty will be in commission. In addition to the ambulances the equipment consists of thirty tent hospitals and several barracks hospitals.

The Bureau of Tuberculosis of the American Red Cross in Paris has been conferring with French authorities in devising plans for the care of the women and children of France that are affected with tuberculosis. The Bureau will shortly begin its work as a special institution. The Edith Wharton Sanitarium for Tuberculosis, which is a separate institution, will be ready for patients by November 15.

Needs of the Red Cross in France.—In response to a request from Henry P. Davison, chairman of the War Council of the American Red Cross, for a general estimate of the money necessary to continue the relief work in France for the next six months, the French Commission has cabled that it will need at least $30,000,000. This is in addition to the $10,000,000 that has already been granted by the War Council. The Red Cross War Council has recently appropriated $31,212 to buy seventy-five tons of food for 100 American prisoners now held in Germany. The soldiers and sailors captured by the Central Powers are not provided by their captors with sufficient food to keep them in good health, nor with sufficient clothing; so the American Red Cross and the United States Government is preparing to feed all American soldiers and sailors who may be taken prisoners during the war.

SERUM TREATMENT OF PNEUMONIA.

FOR years, ever since the Klemperers in 1891 announced that they had produced a serum for the cure of pneumonia, which, however, did not cure, attempts have been making to perfect a specific therapy for this disease. Experiments with animals appeared to demonstrate that they could be immunized against lethal doses of pneumonia by vaccine treatment, and that the serum of such immunized animals was protective in other animals against infection, or even curative when certain precautions were observed. However, it is not always safe to argue from rabbits to man, and the attempts to cure pneumonia in man by similar methods have quite uniformly failed. Much of the insuccess in the earlier experiments was due to the lack of differentiation between the different strains of the pneumococcus. As we now know, there are several strains or types of this bacterium, which differ greatly in their morphology, cultural characteristics, and immune reactions, and the serum derived from one type is hardly more effective in an infection by another strain than would be antimeningococcic serum in such infection. In the case of one strain, indeed, that called *Pneumococcus mucosus*, every effort to produce an immune serum has hitherto given no satisfactory results.

Of all recent experiments in the line of a serum therapy of pneumonia, the most promising are those conducted at the hospital of the Rockefeller Institute by Avery, Chickering, Cole, and Dochez.* They have succeeded thus far in preparing an effective serum only for Type I infections, but for them they appear to have produced a really curative serum. As about one-third of all cases of pneumonia, at least of the cases coming under their observation, are associated with the Type I pneumococcus, it is evident that it is well worth while to have a serum that will cure most of them, reducing the mortality from 25 to 7.5 per cent., or less. The results were actually better than these figures would indicate, for of the eight fatal cases treatment was begun in three only a few hours before death, when they were desperately ill; one recovered from the pneumonia, but died of pulmonary embolism 16 days later; one had an extensive tuberculous involvement of both lungs, and apparently recovered from the slight pneumonic infection, dying more probably of tuberculosis; another was treated late in the disease, and died at the end of nearly eight weeks from a general streptococcus infection. There were, therefore, but two cases in which it could be fairly claimed that the serum treatment failed, and in one of these, an early case in the series, the result was probably due to insufficient dosage. Trials of the serum in other hospitals in New York, Boston, and Pittsburgh have also had satisfactory results, and in a series of 65 cases treated by Major Nichols on the Mexican border last fall only 5 died, showing a mortality of 8 per cent., while of 18 cases of the same type infection not treated with serum 7 died, giving a mortality of 39 per cent.

The results obtained by the use of this serum are, therefore, seen to be most encouraging, but they as yet only hold out a hope of a successful specific therapy of pneumonia, and do not actually promise it. Pneumonia is caused by such a variety of organisms—three distinct types of pneumococcus and a variety of other strains not as yet differentiated, but all grouped under Type IV, in addition to many other bacteria than the pneumococcus—that even were there a specific serum for each one the employment of a polyvalent serum covering all forms of infection would be manifestly impractical. Even in the case of Type I infection, the necessity of a differential diagnosis at the earliest possible moment, and the measures needed to desensitize the patient before giving the serum in the very large doses called for, keep the method out of the category of those adapted to general use. It is available only in hospital cases or in those exceptional ones in private practice in which all laboratory facilities are at the instant disposal of the physician. All these difficulties in the way of a general employment of serum therapy in pneumonia are, however, we may be permitted to believe, only temporary, and one is justified in hoping that these workers, or others inspired by them, will eventually find a remedy for the remaining 66 per cent. of cases of pneumonia, and one that is as readily applicable by the family physician as is the administration of diphtheria antitoxin. That such a remedy is urgently needed cannot be questioned, for lobar pneumonia to-day causes more deaths than any of the other acute infectious diseases, and moreover, as shown by recently published statistics of the Metropolitan Life Insurance Company, its death rate is slowly but steadily rising.

*Monographs of the Rockefeller Institute for Medical Research: Acute Lobar Pneumonia, Prevention and Serum Treatment. By Oswald T. Avery, M.D.; H. T. Chickering, M.D.; Rufus Cole, M.D., and A. R. Dochez, M.D., New York, 1917.

GASTRECTOMY AND GASTROTOMY FOR HAIR BALLS.

TWO unusual cases in which operation was performed for hair balls in the stomach are reported in the September, 1917, number of the *Archives de Médecine des Enfants*. In the first case, which is reported by Dauriac, a total gastrectomy was per-

formed. The second case is reported by Broca, who removed the hair ball by gastrotomy. In Dauriac's case the patient was a poorly developed girl, 13 years of age. Among the findings on examination were the following: The abdomen was somewhat distended and also contained a certain amount of ascitic fluid. The epigastrium was occupied by a large tumor, of woody consistency, movable transversely but slightly fixed in the vertical plane, so that while it could be somewhat displaced upwards it could not be brought further downwards. The lower border of this tumor reached a point about four finger breadths below the umbilicus. The tracing of the tumor on the skin gave the outline of a ptosed stomach. Percussion over this mass gave absolute dullness. The tumor could not be indented at any point, its woody consistency being uniform throughout. In palpating the abdominal wall over the tumor, a crepitation was perceived resembling that of a subcutaneous emphysema, a sign which Dauriac says suffices for the recognition of the existence of a hair ball. The fact that the child could take its food without pain, vomiting, or intestinal troubles turned the attention of the examiners from the stomach and many diagnoses were suggested, including tumor of the spleen or kidney, sarcoma of the ileum and cyst of the mesentery. Exploratory operation showed that the mass felt was the stomach. The stomach walls could not be picked up in folds and appeared to have become a part of the hard mass which, in reality, they enclosed. A diagnosis of sarcoma of the stomach was made and a total resection done with end-to-end anastomosis of the esophagus and duodenum. The child made an uneventful recovery, in spite of the fact that the parents surreptitiously gave her a green apple and some chocolate only six hours after operation. For the first week the child was ravenously hungry and the bowels moved frequently; but gradually the appetite and bowel movements became normal. The child gained weight rapidly and at the end of six months she was fat, rosy-cheeked and healthy, having no trouble whatever from her stomach or, rather, the lack of it. It was ultimately found that from the age of four years the child had been in the habit of pulling out and eating her hair.

When operated upon for hair ball, Broca's patient, also a girl, was but four years old and had already been operated upon once before (November, 1915) because of intractable vomiting followed by refusal of all food. A small mass had been felt in the epigastrium, yet at the exploratory operation no mass was definitely felt in the stomach; but in drawing the colon forward Broca had felt a resistance which suddenly yielded and he believed that he had released an incarcerated coil of intestine. The immediate postoperative course of events seemed to confirm that belief; for the child at once ceased vomiting, took its food well, and grew fat. In April, 1916, a small mass was again found in the epigastrium. By September the mass was much larger and in January, 1917, it had become very large, while abdominal pain and digestive disturbances reappeared. Béclère, upon radiographing the region at this time, stated that the tumor was in the stomach; but Broca, who could not believe that even a sarcoma would have developed so rapidly, thought the case one of omental tuberculosis, and a course of radiotherapy was instituted. The child was rapidly going from bad to worse when it was caught eating a sponge and it was also found that it had the habit of eating hair. Meanwhile, Dauriac's case had been reported; and, in view of the clinical history and radiographic findings, Broca agreed with certain of his colleagues in the diagnosis of hair ball, performed gastrotomy, and removed a mass of hair which nearly filled the stomach and extended 52 centimeters down the intestinal tract. In a note dated June 1, 1917, it was stated that the child is cured, eats and digests well.

Cases of true hair ball, in the stomach are very uncommon and a correct preoperative diagnosis in these cases is still more rare. One of the most interesting cases of this kind was reported by Walton Martin of New York (*Annals of Surgery*, December, 1914), who performed gastrotomy and removed a mass of hair forming a complete cast of the interior of the stomach. In the case reported by Dauriac the *x*-ray was not employed, while in Broca's case radiography was not resorted to before the first operation. If *x*-ray studies had been made doubtless the stomach would not have been removed in the first case, while the second child would have had to undergo but one operation instead of two. The value of the *x*-ray examination in cases where there is even a remote possibility that the stomach contains a foreign body is self-evident.

MODERN CONCEPTION OF BRONCHIAL ASTHMA.

DURING the past two years a very extensive literature has appeared on the subject of bronchial asthma, particularly in respect to its etiology and specific treatment. In view of the large amount of research which has been done by various workers along these lines, it would seem that our conceptions of the disease would have to be recast and amplified. It is now pretty generally conceded that this type of asthma is an anaphylactic phenomenon, that is, it is due to a hypersensitiveness of the human economy to foreign proteins. Such proteins are contained in all kinds of foodstuffs, pollens, animal hair, and bacteria. The two chief portals of entry of foreign proteins are the gastrointestinal and respiratory tracts. On this basis the exciting causes of the asthmatic attack may be divided into the ingested and the inspired types. Included under the latter type is the bacterial form occurring in persons who are sensitized to the different pathogenic bacteria in the respiratory tract.

In a series of papers appearing in *The Journal of Medical Research* during the current year, Walker gives the results of his investigations, the important features of which are the diagnostic cutaneous test and treatment by means of injections of the foreign protein to which the patients are found sensitive. As regards diagnosis, bronchial asthma should be considered anaphylactic when no other origin can be found and when a specific skin test is obtained. Cardiac, renal, pulmonary, and pituitary disease all may cause symptoms which simulate true bronchial asthma. The skin test is performed either as a scarification similar to the von Pirquet tuberculin test, or as an intradermal injection of which the luetin test is a good example. The former is considered to be the most satisfactory, being easy of application and readily interpreted. The method of preparing the various proteins for the cutaneous test is given in detail by Walker. He found that many patients are sensitive to several proteins, a fact that complicates the diagnosis somewhat, but in no way invalidates the test. Walker states that there is certainly a specificity among proteins in the cause and treatment of bronchial asthma and treatment with an indifferent protein or bacteria will not relieve the condition. When an individual is sensitive to food proteins only, the asthma can frequently be relieved by omitting from the diet the particular food or foods which are at fault. Subcutaneous injections of these food proteins at regular intervals do not, as a rule, increase the patient's tolerance for them.

The isolation of one or more organisms from the sputum apparently bears no definite relation to the skin test, so that it is not sufficient to culture the sputum and disregard the individual's skin reaction to the protein of the organism or organisms so isolated. Walker found, however, that a small percentage of asthmatics do not give a characteristic cutaneous reaction with any protein. In some of these cases he was able to demonstrate a positive serum agglutination with *Staphylococcus aureus*, and the patients when treated with vaccines made from this organism showed improvement. Babcock has obtained equally good results from vaccine treatment with an anaerobic fusiform bacillus which he isolated from the sputum as the predominant germ in several cases. In the absence of a positive skin test with the different proteins, it is therefore apparently worth while culturing the sputum and, if a suitable organism is found, trying vaccine treatment. Of course we must not lose sight of the possibility of obscure or hidden foci of infection as a source of protein absorption, especially in infections of the mouth, teeth, and accessory sinuses, as well as in the abdomen where lesions of the gastrointestinal tract may lead to stasis, thus producing protein intoxication. Eradication of such foci and corrective abdominal surgery often relieve and sometimes cure the asthma without further treatment.

THE SOLDIER, THE COURTESAN, AND SYPHILIS.

An anonymous contributor writes at length on this subject in *Le Progrès Médical* for Sept. 1. History, he states, is the perpetual educator of us all, so that to illuminate present conditions we must study the past. Fiaux has recently published a volume on the "Sexual Biology of the Soldier," in which statistics enter largely. Camp morals in past wars have shown great variation. The Duke of Alva had the female camp followers fully organized. Some on horseback, elegantly attired, were intended for the officers, while hundreds on foot ministered to the rank and file. At the other extreme, Strozzi threw eight hundred prostitutes into the river at a single stroke. In a Huguenot army of the sixteenth century the soldiers were compelled to marry the prostitutes. In other campaigns both soldiers and prostitutes were flogged, pilloried, placed in the stocks. Girls were made to run the gauntlet or were daubed with soot or axle grease and exposed on the promenades. None of these stringent measures accomplished the least good because the spread of syphilis was unchecked. It was said late in the eighteenth century that two out of every three soldiers were syphilitic.

At the time of the Revolution three admissions to a hospital for venereal disease were adjudged to render the victim "unworthy to serve his country." The necessity of prompt cure was recognized and the scene was flooded with so-called "specialists" (in reality charlatans), who vaunted their nostrums. Oddly enough, one Boyveau-La Hecteur had a numbered remedy, a mysterious "206." In Berlin when under French rule and in Paris there was an attempt to regulate prostitution, at the same time severely punishing violators of the regulations. In 1814 it was shown that in a supervised house but one girl in seven was infected, while among the clandestines the ratio was one in four. At that period the "soldier's girl" was recognized as a special type of prostitute. These, as a rule, had no home or shelter, were poorly clad and dirty, were glad to get a fee of one or two sous, and at times even a crust of bread thrown from the soldier's window after his return to the barracks. The close of the Napoleonic wars brought about some changes, but the percentage of infections in the troops remained very high. Midway in the nineteenth century the average incidence was 10 per cent, but in some localities it was much higher.

After the Franco-Prussian war, the figures were more favorable, and in 1889 the number of infections fell to about 5 per cent. and in 1895 to 3.75 per cent. The greatest reduction seemed to be in syphilis. By 1911 the ratio was below 2.5 per cent. Both syphilis and gonorrhea were reduced by one-half between 1880 and 1911.

Fiaux apparently does not cover the figures of the present war, although we know that there has been a great increase in incidence. According to him we have only to revert to the measures which

reduced the morbidity before the war, although conditions differ. Before the war the troops were professional soldiers, while today we have to do with a citizen army which sooner or later must be disbanded.

Oatmeal Gruel in Infant Feeding.

Oats have always held a high reputation as a nutritive food for man and beast. Oats contain a higher percentage of carbohydrates and fat than other grains, and, moreover, the fat in oats is of better quality than that in other grains, and the iron content of oats is very high. Oatmeal gruel is an excellent food for infants, and was first used in this capacity by the French. At the present time, oats are being used extensively for well and sick adults, and especially for well and sick infants and children, in the form of oatmeal gruel. Dr. A. Levinson, in the *Archives of Pediatrics*, gives the results of investigations taken by himself and colleagues as to the value of oats as an infant food. He summarizes as follows: (1) Oats is an important addition to infant food. (2) The most valuable preparation is oatmeal gruel. (3) The 5 per cent. mixture, which contains 1.5671 grams, dry substance and equals 5.4 large calories in 100 c.c., is the most efficacious preparation. (4) Oatmeal gruel can be prepared very simply by washing grits in cold water and boiling for 30 minutes and then straining. (5) Gruel can be given at any age with beneficial results. (6) Its taking increases the appetite of the child. (7) It makes the stool homogeneous. (8) It often relieves constipation. (9) It has high iron content. The experiments carried out by Levinson were mainly in order to find out if oatmeal gruel had a favorable effect upon the stool of infants. As will be observed above, the conclusions from this point of view were eminently satisfactory.

News of the Week.

America May Use German Patents.—The Federal Trade Commission has issued regulations under which German-owned patents and copyrights will be licensed for manufacture by citizens of the United States. After the regulations were made public the commission conferred with a group of medical men to consider the licensing of certain drugs and non-toxic substitutes for local anesthetics of which the supply in this country has run dangerously low. Approximately 20,000 patented and copyrighted articles are said to be affected by the commission's orders. It is said to be likely that any licenses issued for the manufacture of drugs will carry a provision that a certain percentage of the output be turned over to the Public Health Service. The regulations follow the law closely in safeguarding the interests of patent owners, who must be reimbursed for the use of their inventions, and licenses will be issued only where the interest of the public demands it.

Widespread Epidemics in Germany.—A press correspondent, who is with the French Armies near Verdun, reports that thousands of letters have been taken from German prisoners which describe in harrowing terms the ravages of dysentery, cholera, and typhus fever in Germany. These letters bear witness to the prevalence of such epidemics at Cologne, Mülheim, Coburg, Burgstädt, Guben, Alakenbourg, Langen, Lichtenberg, Staltach, Altona, Wiesbaden, Grunewald, and many other German cities. It is reported that over one-half the letters taken from the prisoners contain some reference to the spread of these epidemics. The deduction seems to be warranted that if these letters have been allowed to pass the censors the actual conditions must be much worse than those mentioned which have been allowed to pass.

Wants Federal Control of Habit-Forming Drugs.—Police Commissioner Woods of New York has entered a protest against the loose method of enforcing the law against the indiscriminate sale of habit-forming drugs which makes it extremely difficult to prevent the traffic in these drugs in New York. He has written to the Attorney-General urging additional Federal legislation for the purpose of curbing the "alarming increase" in the traffic in these drugs. Commissioner Woods wants the sale of habit-forming drugs placed directly in the hands of the Federal Government, with zone districts created for their distribution, and severe penalties for alteration of certificates calling for drugs. He states that on an average 2000 arrests of drug users are made annually in New York City.

Tetanus Germs in Vaccine.—A report from St. Paul, Minn., states that vaccine sent there for use in vaccinations against smallpox was followed by a request for its return, as there was a possibility that it contained tetanus germs. The vaccine was sent to Washington for analysis. At the same time it is reported that smallpox vaccine used in the inoculation of the members of the Albany Base Hospital Corps, which expects to sail for France any day, contained tetanus germs. Orders have been sent from Washington that all the men who were inoculated with this vaccine be inoculated again with tetanus antitoxin. Military authorities, though reluctant to discuss the matter, entertain the suspicion that it is another evidence of German barbarity.

New York State Prison Population.—The total prison population of New York State is 5924. This is apprecibaly less than that of a year ago. The decrease is explained as due to prosperity and the war.

Automobile Accidents More Fatal Than Typhoid and Scarlet Fever.—A recent communication from the New York State Department of Health calls attention to the fact that automobiles killed more people in this State during the first nine months of 1917 than did typhoid and scarlet fever combined. During the month of September automobile accidents in New York State caused 155 deaths —more than the combined mortality by intentional murder and suicide. It is also notable that the greater portion of deaths from this cause occurred in streets and highways of up-State districts, the distribution of deaths being: New York City 55, up-State cities 63, and rural districts 37. The number of deaths from automobile accidents in the State thus far in 1917 has been 775, which exceeds the number for the corresponding period

of any previous year. The mortality from automobile accidents, and likewise typhoid fever, is usually highest in September. The latter, however, has maintained the low record made in 1916. September, 1917, recorded 796 cases of typhoid fever, with 84 deaths in the entire State, which represents a decline of 28 per cent. in the number of cases and 26 per cent. in the number of deaths. For the year 1917 there have been reported, up to September 30, 2,840 cases and 590 deaths, compared with an average of 3,934 cases and 590 deaths for this period.

Harvey Society Lecture.—The second of this series of lectures will be delivered at the New York Academy of Medicine on the evening of Nov. 10, at 8:30, by Dr. Carl L. Alsberg, U. S. Department of Agriculture. His subject is "Current Food Problems."

Evening Clinic for Genito-Urinary Diseases.—The Polyclinic Hospital announces that it has established a dispensary service for the treatment of genito-urinary diseases in the male. These clinics are held Tuesday and Saturday evenings.

Milk for Russia.—The American Red Cross has purchased one million pounds of condensed milk for the babies of Russia. This consignment is to be shipped immediately and an equal amount will follow next month. This appropriation was made in response to an urgent request from the Red Cross Commission in Russia.

The Hebrew Orphan Asylum of New York City has selected a site in the Wakefield Section of the Bronx for new buildings which it proposes to erect in the near future. The site is 100 acres in extent and it is estimated that the entire cost of the new home will be $1,000,000.

Three Full-Time Medical Positions.—Framingham, Mass., has three full-time medical positions now open. These include a public school medical supervisorship, a medical position in one of the city's large industries, and a medical position at the head of an industrial medical organization for the community as a whole. The first two positions will pay $2,500 a year, and the third $3,500. Men with industrial experience are preferred, though young men with a sound medical background will be considered. Further information may be obtained from Dr. Donald B. Armstrong, executive officer of the Community Health Demonstration, Framingham, Mass.

Assistant Medical Officer.—The Civil Service Commission of the State of New York announces an examination for the position of assistant medical officer, Department of the Health Officer of the Port of New York. The position carries a salary of $1,500 and requires residence and service at one of the quarantine islands of the lower New York Bay. Applications must be in the office of the Civil Service Commission, Albany, N. Y., before Nov. 28. Preference will be given to those having a knowledge of cholera, plague, yellow fever, smallpox, leprosy, epidemic cerebrospinal meningitis, and typhus fever.

Physiological Chemist and Laboratory Assistant in Bacteriology Wanted.—The Civil Service Commission of the State of New York announces examinations for these positions, for which degrees in medicine are not required. Applicants for these positions must have a degree from a college maintaining a standard satisfactory to the Commission or an equivalent education and special training in these respective lines. The position of physiological chemist pays a salary of $1,500; that of laboratory assistant in bacteriology, $720 to $1,200. Applications must be in the office of the Civil Service Commission, Albany, N. Y., by November 28, 1917.

Examination for Superintendent of Sea View Hospital.—The New York Municipal Civil Service Commission announces an examination for medical superintendent of Sea View Hospital, Staten Island, N. Y. Applicants must present evidence of graduation from a recognized medical college, one year internship in a general hospital and one year's experience as an officer in an institution for the treatment of tuberculosis or equivalent executive experience in public health work. The position pays a salary of from $2,100 to $2,490 a year. Applications must be filed with the Municipal Civil Service Commission before November 13, 1917.

The Fifth Conference of Industrial Physicians and Surgeons, Department of Labor and Industry, will meet in the State Capital, Harrisburg, on November 20, 1917. Copies of the program may be obtained from Dr. Francis D. Patterson, 506 Kunkle Building, Harrisburg, Pa.

The Medical Inspectors and Physical Educators Association of the State of New York will meet at a place to be designated at one of the sessions of the Section on Hygiene and Physical Education of the New York State Teachers' Association, at Syracuse, on November 26, 27, and 28. The purpose of this meeting is to elect officers of the State Association for the following year and vote upon the constitution of the Association.

The Radium Sanatorium of New York has secured the services of Miss Bianca de Vitalis as superintendent. Miss de Vitalis is a graduate of Essex County Hospital of Newark, N. J., and Fordham Hospital of New York, and for several years has been a prominent figure in many philanthropic organizations.

Dr. E. Styles Potter has been appointed visiting surgeon in the Genito-Urinary Department of the West Side German Dispensary.

Dr. Byron C. Darling has removed to 103 Park Avenue, New York City.

Obituary Notes.—Dr. JOHN MILTON DEXTER, a graduate of the College of Physicians and Surgeons in 1894, aged 50 years, was run over and killed by an automobile while crossing a street near his home in New York City, on Nov. 1.

Dr. HENRY ALLERS of Harrison, N. J., a graduate of New York University Medical School, in 1881, died on Oct. 30, aged 61 years.

Dr. EDWIN D. NEWTON of Athens, Ga., a graduate of Jefferson Medical College, Philadelphia, Pa., died of pneumonia on Oct. 19, aged 82 years.

Dr. JOSEPH JAMES HARRISON, one of the oldest physicians in Tennessee, died at his home in Loudon, Tenn., after a brief illness, at the age of 84 years.

Dr. ALBERT NATHAN, a graduate of the medical College of South Carolina, in 1909, and a practicing physician of Charleston, S. C., died in Boston, on Oct. 22, aged 30 years.

Dr. WILFRED H. SAGE, a retired physician of

Boston, and a graduate of the Buffalo University Medical School, died at the residence of his daughter in Medford, Mass., on Oct. 26, aged 63 years.

Dr. ELBRIDGE A. SHAY, a graduate of the Cleveland University of Medicine and Surgery, in 1883, died at his home in St. Louis, after a long illness, on Oct. 20, aged 68 years.

Dr. ALONZO G. TRAFTON of South Boston, a graduate of the Medical Department of Bowdoin College, in 1877, died on Oct. 28.

Dr. DANIEL TROTTER, a graduate of the Medical College of Atlanta, Ga., in 1913, died at his home in Madison, Ga., on Oct. 16.

Dr. NEWELL B. BURNS, a graduate of Harvard Medical School, in 1909, died at the State Sanitarium at North Reading, Mass., with which institution he was officially associated, on Oct. 29, aged 35 years.

Dr. THOMAS SCILLES KENNEDY, died at his home in New Orleans, La., about Oct. 18. He served during the Civil War, was a graduate of Tulane University, La., in 1869, and was for fifteen years in charge of the Children's Clinic of the Charity Hospital.

Dr. JOHN KOLMER, a graduate of Jefferson Medical College, in 1894, died after a long illness, at his home in Indianapolis, aged 51 years.

Dr. SILAS D. PRESBREY died at his home in Taunton, Mass., on Oct. 23, at the age of 79 years. He was a graduate of Harvard Medical School, in 1865, city physician of Taunton for some years, and took a leading part in the establishment of the Morton Hospital.

Correspondence.

OUR LETTER FROM PARIS.

(From Our Regular Correspondent.)

AN AMERICAN FIELD HOSPITAL—TUBERCULOSIS AND THE RED CROSS.

PARIS, October 1, 1917.

I HAVE just returned from a short trip and during my absence visited a field hospital and can testify to the splendid organization of our medical corps. Our boys are well cared for and Americans at home may rest assured that the system is so well studied out that no matter where the army moves to, or how often, the hospital arrangements will be perfect. In two hours the hospital I saw could be packed up and sent marching to another place, having all its equipment ready for service. The different huts were kept at proper distances from each other, so as to avoid spreading such maladies as measles, mumps, and so on. The surgical huts were spick and span. Some of the men are so energetic that they sprain muscles, sometimes, or hurt a hand or foot or fall and fracture a bone. But the men I saw seem to take such things as part of the business and were as jolly as could be.

Every day men arrive for treatment and every day men are discharged cured. The air is good, the food of the best America can send out to us, and there is an atmosphere of efficiency, cheerfulness, and friendship everywhere that helps the cure and gives the men plenty of sympathy. Many of them were playing football, others were playing checkers, some were reading papers.

The Y. M. C. A. is doing good work here and sending the men games and implements for sport of different kinds so as to suit all tastes.

By going among the convalescents I had a chance to learn some of their views. One said he could not make out why he did not get his letters delivered to him. Another complained of the parcel delivery arrangements. He had received letters saying that his mother had sent him different comforts, but he never got them. Another complained because in the neighboring village or town the Americans were charged higher prices than the natives. This was a pretty general grievance. Our men cannot see why the natives do not treat them more as friends and less as millionaires ready to spend extra money for little comforts.

The men need cheerful news and constant encouragement in their life abroad doing something for the cause. One man said: "It's all right when you don't think of it," which is just the psychological point our people at home can well remember. Another said: "Tell our folks that they needn't get gloomy over our life here. Tell them we are well and happy and have no time for worry. We are having a mighty fine time." The work is serious enough without reminding the men of what they left behind them. What was to be noticed throughout the rank and file everywhere was the extreme courtesy, the desire to help each other, the readiness to answer questions, to show you the way anywhere or tell you to whom you ought to go for information; the pleasant smiles of our boys who pass and recognize you as a friend and a fellow countryman; the modesty and simplicity of the officers, who give all their time to their responsibilities and yet have time to be courteous and chivalrous, as our American traditions are observed.

Commenting on the improvement in the standard of the men composing the present army, an officer said: "The class of men in our army now is far ahead of anything when I was a young man. Here in the hospital, I observe our men at my ease and study them, and I can tell you they are a fine lot of fellows. They are intelligent and well educated. The American soldiers are not improvident; they send their money home and put away their savings. You see them grouped together, very often discussing war problems, making maps of maneuvers, and arguing points of tactics. They are soldiers right enough. They have military genius among them, and you will see this made good as the war develops."

An occasion indicating the splendid relations existing between France and America, and between the American Red Cross and other organizations in France, took place when the activities of the Tuberculeux de la Guerre were transferred to the American Red Cross. The Tuberculeux de la Guerre was one of the earliest organizations to undertake the great fight against tuberculosis in France. It is only because, in conjunction with the Rockefeller Foundation, the Red Cross is making large plans for the care and prevention of tuberculosis that it felt justified in accepting this very generous offer. Large projects have been formulated and are under way. Sanatoria and hospitals are essential parts of any such large organized plans for dealing with tuberculosis in France,

and it is highly desirable that all sections of the organization should be thoroughly coordinated. This being the case, the American Red Cross accepted the very generous offer of the Comité des Tuberculeux de la Guerre, assumed the development of the work now under way, and pledged itself to carry on this work for the care, cure, and prevention of tuberculosis.

5. Changing Methods and Advances in the Treatment of Progressive Deafness from Chronic Secretory Otitis Media.—Francis P. Emerson says that, for the reason that otology is not an exact science, there are problems connected with its practice that should be reconsidered at stated intervals. One of these is the diagnosis, prognosis and treatment of that form of progressive deafness which is the result of chronic secretory otitis media. As a result of detailed study he states that (1) Every case of chronic progressive middle ear deafness has a primary focus, which persists as a low-grade infection, subject to acute exacerbations. In chronic cases such foci are usually multiple. (2) Such primary focus is usually constant for the individual, and is indicated by the location of exacerbations. (3) Every case showing variable hearing can usually be improved up to their best hearing, or more. (4) So-called cases of nerve deafness of non-specific origin are in the experience of the writer due to toxemia from some definite focus. (5) Inflation in *chronic cases* is unscientific and harmful as a routine, as the tube is already open and has partly lost its tone in the majority of cases; and in those cases not open, it does nothing to remove the cause. (6) Nasal obstructions do no harm to the middle ear unless infection is present. Such obstructions, however, are the primary cause in the development of imperfect drainage, which predisposes to infection, and which is always present in cases of chronic secretory otitis media originating in the nose. (7) Foci, whether in the sinuses, tonsils, mandible or epipharynx, are potential factors in the progress of chronic progressive otitis media, either by direct extension or through the lymph and blood streams. (8) No hearing test will forecast the improvement in a given case as long as we have a positive Rinné with variable hearing. (9) Whatever the macroscopic appearance of the membrana tympani, the cause of the deafness is active for a long time outside the middle ear as a toxemia, or low-grade infection subject to acute exacerbations. (10) Constitutional diseases have but little effect upon the course of chronic secretory otitis media, except to lower the patient's resistance and make him more susceptible to exacerbations of his localized focus or foci.

1. War Tetanus.—Leon H. Cornwall states that although the major symptoms of war tetanus are familiar to most medical men it is surprising how frequently the early symptoms are overlooked. In the case of the army surgeons in the field this is not to be wondered at when one considers the number of duties required of officers of the Medical Corps. Early symptoms which often give rise to the first clue are profuse perspiration, vertigo, and difficulty of urination. The masticatory spasm which leads to trismus and contracture of the neck muscles is the forerunner of opisthotonus; the spasm of the breast and diaphragmatic muscles with the accompanying pain resembling pleurisy will many times not be enough for the patient or physician, because the wounded soldier in his patience and without knowledge of the danger minimizes these symptoms and concentrates his attention on the healing of the wound. The physician may suddenly discover that he is dealing with a case of severe general convulsions or one morning may find his patient suffering from intermittent convulsive attacks or in the condition characteristic of the spasm of the whole body musculature. That he stands by the bed of a tetanus victim will occur to him with a shock. With reference to the toxin present Cornwall states that from the wound the toxin passes along the pathways of the nerves, probably following along the perineural sheaths to the spinal cord. It may be absorbed by the blood and lymph capillaries and reach the cord indirectly, being taken up by the end plates of the motor nerves. The central nervous system and peripheral nerves do not take up the antitoxin in the same way as they do the toxin. A high antitoxic content of the blood will not protect an animal if the toxin is injected into a nerve and not subcutaneously or intravenously. The antitoxin can only neutralize that part of the toxin unabsorbed at the point of injection or that portion which is in the bloodstream and ununited with the nerve endings. A cure can only result if before the antitoxin injection a lethal dose has not been taken up by the nervous system. The result depends upon the interval between the toxin and antitoxin administration. The amount of antitoxin which, injected intravenously simultaneously with the toxin, will protect the animal against many times the lethal dose of toxin, fails if a few minutes elapse between the toxin administration and that of the antitoxin. After one hour forty times the amount of antitoxin is required that would suffice if given at the same time or immediately after the toxin, whereas after five hours six hundred times the dose of antitoxin necessary to neutralize the toxin *in vitro* fails. After a lethal dose of toxin is absorbed by the peripheral nerves only a direct injection of antitoxin into the affected nerve can hinder extension to the centers. If the centers are affected a very large dose of antitoxin subcutaneously is worthless. The bacillus of Nicolaier does not occur alone in wounds, but has associated with it many others. Among these are the pyogenic cocci, *Bacillus aerogenes capsulatus* of Welch and the *Vibrio septique* of Pasteur, the cause of malignant edema. The anaerobes play the leading role in the secondary infection of wounds of battle. The treatment consists of three varieties: general, local, and regiminal. The general treatment consists of the use of antitoxin and drugs. Locally the treatment includes the use of antitoxin for its neutralizing effect, antiseptic surgical care, and the injection of medication with bactericidal action such as phenol and peroxide. Absolute quiet comprises the major part of the régime. The merits of antitoxin are so generally accepted that its use as a therapeutic measure needs no defense. It is the immunizing and curative agent *par excellence*. There are several methods of administration, however, which should be appreciated as the indications for their use differ, certain cases requiring a combination of all methods. For the administration of antitoxin four methods are employed: subcutaneous, intravenous, intraspinal, and endoneural. In every wound contaminated by dirt or pieces of clothing and especially wounds of the extremities a prophylactic injection of 1,000 to 2,000 units should be given subcutaneously at or near the site of injury. Owing to a difference in the methods of the standardization of antitoxin units in this country and abroad the dosage is not the same. In Europe twenty units constitute the dose for prophylactic purposes. The value of the local injection of antitoxin in prophy-

laxis is due to the fact that it prevents the absorption of the tetanus toxin from the wound by combining with and neutralizing it. If, however, the toxin has been absorbed by the nervous system this method is of no avail. One initial prophylactic dose is not sufficient, but should be repeated weekly for three doses or until the wound is healed. Cornwall draws the following conclusions as a result of his work: (1) Tetanus is a common scourge of war. (2) In the present war there have been more cases of tetanus per 1,000 than in any previous war. (3) Tetanus develops after wounds contaminated by dirt and clothing and is more frequent regions. (4) The usual incubation period is from six to sixteen days, but in tardy tetanus may be prolonged after wounds of the extremities than those of other regions. (4) The usual incubation period is from six to sixteen days, but in tardy tetanus may be prolonged to three months. (5) Low temperatures and free excess of oxygen prolong the period of incubation. (6) The onset is frequently so insidious as to render early diagnosis difficult. (7) The pathway of the infection is along the perineural lymph channels to the spinal cord. (8) Early prophylactic injection of antitoxin should be given in every wound contaminated by dirt or particles of clothing. (9) For therapeutic purposes the serum should be given subcutaneously, intravenously, intraspinally, and endoneurally. (10) To prevent the muscular fatigue due to spasms and convulsions sedatives are of great value and absolute rest is of paramount importance. (11) So called tardy tetanus may occur as late as three months after injury and is especially likely to follow secondary surgical operations or other trauma at or near wounds previously infected with tetanus bacilli. (12) The prognosis is grave when the disease develops early, but late cases have a favorable prognosis.

9. A New Complement Fixation Reaction as Applied to Leucorrhea: A Comparative Study of Forty-Seven Cases.—Louis D. Smith and F. Lee Stone state that the difficulty of making an absolute diagnosis of gonorrhea in woman by a combination of clinical history, signs, symptoms and the usual laboratory methods has led them to undertake a comparative analysis of forty-seven cases of women suffering from leucorrhea, employing the usual methods and the complement fixation test devised by one of them (Smith). In entering on these experiments, they were immediately impressed with the insecurity and lack of value of all ordinary methods to serve as a criterion for diagnosis to substantiate their findings. For who, by the usual methods at command, can with absolute assurance delegate a woman suffering from leucorrhea to the categorical diagnosis of gonorrhea? In conducting the special test, it was deemed advisable, in order to eliminate bias, to do so without a knowledge of the nature of the case. Accordingly the specimens were submitted in serial numbers to one of them (Smith), and the other data were kept separately (Stone) until after the report of the test, when all ascertained facts were coordinated. In this manner the special test under trial was performed without any guiding influence, and the other laboratory examinations were made without knowledge of the outcome of this test. The principle of the test involved is that of the Bordet-Gengou complement fixation reaction. In their test the antibody of the bacteriolytic system is supplied by commercial antigonococcic horse serum, and the antigen is the unknown element. This antigen is embodied in the suspension of the leucorrheal discharge which, although gonococci may be few, nevertheless contains the products of their interaction with the tissue and also their own autolytic products. In other words, the principle of the Wassermann test is reversed, in that in the latter the unknown element is the antibody in the patient's blood, and the known antigen is tissue extract, whereas in our test, the antibody is supplied, and the antigen (identical with the gonococcus or its products) is the unknown factor. Thus employing principle it is possible to determine at its very inception a gonorrheal infection in male or female, and similarly to determine the time of disappearance of the organism according to experiments we are now conducting. A specimen of the discharge is collected from the cervix and vagina on a long cotton swab. The swab is immersed in about 2 c.c. of physiologic sodium chlorid solution. The discharge is freed from the swab and ground finely with the sodium chlorid solution in a glass mortar. The suspension thus prepared is permitted to stand over night and then heated at 56 C. (132.8 F.) for half an hour. In appearance a properly prepared suspension exhibits a faint turbidity, to obtain which it may be necessary to add more sodium chlorid solution. Practice will enable one to determine the proper dilution. Floating particles may be removed by a few seconds of centrifuging. In the test a positive and negative control should be used, each specimen requiring ten tubes (as used in the Wassermann test), consisting of a first and second row of four tubes, and single tubes in the third and fourth rows. In all tubes are placed 2 c.c. of physiologic sodium chlorid solution. To the first tubes of the first and second rows is added 1 minim of the suspension, in the second tube 3 minims, in the third 5 minims, in the fourth 7 minims. In the single tube of the third row are placed 7 minims of the suspension. In all the first row tubes and the single tube of the fourth row is now placed 1 minim of the properly standardized antigonococcic serum. In all tubes excepting the single third row tube is now placed guinea-pig serum (complement) as is done in the Wassermann test. The specimens are now incubated in the water bath for one-half hour at 37 C. (98.6 F.), when the antisheep amboceptor and sheep corpuscles are added and reincubated. Readings are then taken. The first row constitutes the test, the degree of inhibition of hemolysis indicating the degree of positiveness, if the corresponding second row, which is the control for the test row, has completely hemolyzed. The third row tube is a control on a possible hemolytic tendency of the specimen to be tested, whereas the fourth row tube is a control on the anticomplementary action of the antigonococcic serum. Results show that in only two instances was a negative test obtained when there was evidence of gonorrhea, one of these having presented a bartholinian abscess that had been cured. However, in these two instances slide examinations and blood complement fixation tests were negative. In seventeen cases with positive clinical evidence and negative slide examinations, our complement fixation reaction was positive. In four cases without clinical appearance of gonorrhea, the test was positive in two and doubtful in two. Five cases doubtful clinically yielded positive reactions. Three cases with positive clinical evidence and positive Smith test exhibited positive blood complement fixation reactions. In view of the fact that we have no real basis for comparison of the test under discussion, time and additional work are necessary to establish its value. It is feasible theoretically because it involves the principle of the Bordet-Gengou complement fixation reaction. In their experience it has been of great value in confirmative diagnosis of gonorrheal infections. It has served, finally, as a guide in determining cures.

2. A Comparative Study of the Reactions to Human and Bovine Tuberculin Applied by the Method of Von Pirquet in Cases of Tuberculous Disease of the Bones and Joints.—H. J. Gauvain states that the work here reported was done for the Local Government Board, London. Bacterial reports were made on 116 cases of children suffering from tuberculous bone or joint diseases. As a matter of interest it was decided to undertake a quantitative investigation of the von Pirquet cutaneous test on such of these patients as were available to check the reactions by color photographs and to endeavor to ascertain: (1) Whether the reaction to cutaneous inoculations of tuberculin was constantly present in patients suffering from undoubted tuberculous lesions of the bones or joints—that is, in patients from whose lesions the tubercle bacilli had been isolated. (2) If not constantly present, under what circumstances the reaction would not appear. (3) Whether by using both human and bovine tuberculin for the von Pirquet test it would be possible to ascertain, from the reaction which followed, whether the patient was suffering from tuberculosis of human or bovine origin. (4) Whether the degree of reaction gave any indication of the severity of infection. (5) The extent and nature of the reaction. The von Pirquet test was applied to 80 out of the 116 cases. In order to avoid any risk of unconscious bias the inoculations were made and results recorded without the knowledge of bacteriological reports as to the type of bacillus found. The tuberculins employed were Koch's "old tuberculin," prepared from the "human" type of bacilli, and his tuberculin prepared in identical way from bacilli of bovine origin. The tuberculins were applied to suitable skin scarifications in dilutions of 1/64, 1/16, ¼, and in full strength, each in approximately equal bulk and controlled by inoculation of a scarification with the same quantity of sterile normal saline solution. In the majority of cases the scarifications were made on the anterior surfaces of both thighs; where the legs were not available both arms were used. In every case a minimum distance of at least two inches existed between any one scarification and its nearest fellow, so that adjacent reactions should not become confluent. To minimize the possibility of tuberculin applied to one scarification being conveyed by the lymphatic channels to a neighboring scarification which had been treated with a weaker solution of tuberculin the solutions, commencing with the control, were applied to the scarifications in order of increasing strength from the distal to the proximal extremity of each limb. Human tuberculin was always applied to scarifications on the right side of the body and bovine tuberculin to scarifications on the left side. The control solution and the tuberculins were all applied to the scarification marks with sterile glass eye-rods of the same size, a separate rod being kept in each bottle. In this way approximately the same quantity of liquid was applied to the center of each scar. The solution was simply placed on the scar, not rubbed in. The bottles containing the solutions of tuberculin were all placed on one tray in ascending order of strength. On the right-hand side of the tray was the human tuberculin, on the left the bovine. In the middle was the bottle containing the control solution. The bottles had distinguishing colored labels as a further safeguard against the possibility of introducing the wrong solution into the various scarifications. Gauvain states also that the final result of the investigation may be stated briefly as follows: (1) Local reactions to inoculations of both human and bovine tuberculin were invariably present in all patients from whose pus tubercle bacilli had been isolated. (2) Though reactions were invariably present the degree of reaction varied within wide limits. (3) Weakly and cachectic patients usually reacted feebly, quite irrespective of differences in the severity of their local lesions. (4) Strong and vigorous patients exhibited wide differences in the degree of their reactions, irrespective of differences in the extent or the severity of their local lesions. (5) The quantitative von Pirquet test was not found to be of value in forming an estimate of the severity of the infection, and was of little prognostic value. (6) It was impossible to differentiate the type of tubercle bacillus with which the patient was attacked by the nature of the reaction to the tuberculin employed.

5. Five Hundred Consecutive Cases of Acute Gonorrhea Treated with Vaccines; and a Note on the Electrochemical Method.—N. P. L. Lumb states that after treating a large number of cases of gonorrhea it seemed that the only way of eradicating the disease was to attack it through the blood, in the same way as with salvarsan in syphilis. The administration of many thousand injections of a particular stock vaccine (Staphgon) prepared at this hospital brought to light one most encouraging fact, namely, the appearance of a visible discharge from the urethra or signs in the urine shortly after the injection of a moderate dose when the cure was not complete, or in other words, when the patient was not free from active gonorrhea. This is referred to in Colonel Harrison's manual on the subject as one test of cure, and in my experience it has proved very valuable. The return of the discharge can only be due to gonococci reappearing at the surface of the urethral mucous membrane, and it is reasonable to suppose that the vaccine has reached them through the blood stream, rendered them uncomfortable, so causing their migration from the deeper tissues to the surface. This, then, is a means of attacking the gonococci through the blood stream in the acute stage of the disease, and of penetrating tissues which the irrigating fluid cannot reach. By giving suitable doses of vaccine the hostility of the blood is increased to a maximum, while irrigation washes away the inflammatory products. The administration of a vaccine as a routine form of treatment in the *acute* stage of gonorrhea has not up to the present been generally adopted, and he has thought it worth while to bring the results to notice. Both in regard to dosage and the period of time between successive injections experimental evidence had to be accumulated, and the effect produced by varying these two factors was observed in several hundred cases before finally deciding in favor of the method now to be described, which differs considerably from that usually adopted in the chronic stage. In the first fifty cases treated the discharge had been present for at least a week before the patient presented himself for treatment and the disease was consequently well established. The rationale of the method used is as follows: (1) To affect the blood as early as possible, with a view to (a) Antagonizing the gonococcus; (b) diminishing the likelihood of complications. (2) To get as big an action as possible *in the shortest time* without inducing a negative phase. Two main lines of treatment were adopted: Intensive dosage with a mixed stock vaccine of gonococci and staphylococci, and weak irrigation on Janet's system. After the treatment of the first fifty consecutive cases, Lumb revised the method of treatment, which is as follows: On the first morning after admission a two-glass urine test is made, the urine of six or seven hours being passed into two conical glasses on rising in the morning. About four ounces are passed into one glass and the remainder of the bladder contents into the second one. The patient stays in bed for the first three days, getting up

only to irrigate in the morning and again in the afternoon. Milk diet is ordered and an unlimited quantity of barley water allowed. Aperients are given regularly as necessary to keep the bowels freely open. Irrigation is commenced with 1 in 8000 potassium permanganate on Janet's system, the container being placed five feet above the patient, who is instructed to thoroughly wash out the anterior urethra first and then to get the solution into the bladder. A dose of 50 million gonococci with 150 million staphylococci is given on the first morning, and urotropine, according to the following formula, for five days: Urotropine gr. x, Aq. ad ℥ j, Ac. sod. phosphat. gr. xx, Potass. citrat. gr. x, Syr. aurant. ℥ ss, Inf. buchu ad ℥ j. Dose: One ounce of each, mixed just before taking, three times a day. On the second day irrigation is carried out morning and afternoon as before, and the vaccine is given again on the third morning, the dose being 100 million, or 2 c.cm. By the fourth day the discharge in most acute cases has diminished to a small drop and the patient is allowed to get up and go about as usual, taking a moderate amount of exercise. He now irrigates with 1 in 6000 potassium permanganate, and the diet becomes an ordinary one, except that fish or *a small quantity* of meat is allowed, alcohol and condiments being forbidden. On the morning after getting up a four-glass urine test is made and used as the guide in further treatment. On the sixth day the medicine is stopped and another dose (100 million) of gonococci given, irrigation being continued as before. The patient then passes a two-glass urine test, as already described, on alternate days, and the treatment is modified as considered necessary. On the ninth day he receives 100 million gonococci, and a bougie is passed on the tenth day, the urethra being massaged if the glands are involved. The bougie at this stage is valuable in three ways: (1) It allows the massage of Littre's glands. (2) It reveals any tendency to stricture. (3) It has a stimulating effect on the mucous membrane. On the twelfth and fifteenth days two more doses of 2 c.cm. are given. The urine in both glasses is clear, though the first one may still contain a few flakes. The patient at this stage is taking as much exercise as possible, playing games every afternoon and eating a full diet. If under these conditions no discharge be apparent, the irrigation is changed to 1 in 1000 zinc sulphate or 1 in 4000 zinc permanganate for two or three days, and then all treatment stopped. The urine is examined as before and a final dose of 50 million gonococci given two or three days after all treatment has ceased. If the patient be not free from active gonorrhea, this "provocative" dose invariably gives rise to signs in the urine, or an obvious discharge within 24 hours, and this is a most valuable test. If the urine remain clear after this, the case is watched for another three days and then considered clear. No further injections are given for ten days. At the end of that period a second course of six injections may be commenced, the dose remaining at 2 c.cm., and the interval between each injection being two clear days. Many cases require one course only, others two, the latter particularly when complications are present. At the end of the first course of vaccines the two-glass urine test usually shows that the patient is practically free from discharge, apart from a little muco-purulent secretion in the morning. Irrigation is continued until nothing is seen at any time, even after vigorous exercise, and then stopped altogether. The test dose of vaccine (100 millions) is given, and the urine examined for six or seven days afterward. If no discharge reappears the patient is considered to be clear. Owing to existing circumstances it has not been practicable to examine urethroscopically every patient before leaving hospital, but in a considerable number this was done. With regard to the second course, it should be made clear that the whole of the six injections are frequently not required. When the urine is free from flakes and no discharge is seen at any time, irrigation is stopped and the test dose of vaccine applied. Should a discharge reappear, indicating that the disease has not been eradicated, the remaining number of vaccines to complete the six is given, and then a second interval of ten days allowed to elapse. Irrigation and local treatment have been carried out in accordance with the original scheme. The results of 500 consecutive cases show that 278 cases were uncomplicated, while 222, or roughly 44 per cent., were complicated. This is accounted for by two factors: (1) Active service; (2) lateness in reporting. A patient contracting gonorrhea often does not realize the condition until the discharge is profuse, and during that time a spell of hard work will do much harm. Also a number delay reporting to the medical officer in the hope that the discharge will disappear. Thus of 101 epididymitis cases in the series of 500 acute cases 70 were present on admission and 8 of the 10 arthritis cases. Of the prostatitis cases the exact number present on admission cannot be stated, since routine examination of the prostate was not carried out until the end of the second week of treatment. An analysis of the uncomplicated cases shows that 60 per cent. were under treatment 30 days or less, with an average of 19 days. The average duration for the whole of the uncomplicated cases (278) was 35 days, or 5 weeks. The complicated cases show clearly the importance of thorough treatment of the prostate, the cases of prostatitis requiring, on an average, 10 days longer than those of arthritis, and 22 days longer than those of epididymitis. The longest cases of all were those in which acute prostatitis was followed by acute epididymitis, this group forming 3 per cent. of the total. The average stay of all complicated cases was 52 days, or several days under 2 months. It has from time to time been suggested, though never with adequate proof, that vaccines are dangerous in the acute stage, and lead to complications. If this were so it would have been expected that in this series of 500 acute cases, all treated from the start with big doses, a large proportion of complications would have developed, especially epididymitis and arthritis. This is not the case. Of the 101 epididymitis cases 70 were present on admission, leaving 31 developed out of 430 cases, that is, 7 per cent. Of the 10 arthritis cases 8 were present on admission, leaving two developed out of 490 cases, that is, less than 1 per cent. The most remarkable feature of all is the exceptionally low percentage of relapses. Out of the 500 cases two only have occurred during a period of 4 months after completion of the series. Many of the cases left hospital more than 6 months ago. This gives a relapse rate of less than 1 per cent. It is a very satisfactory proof of the value of vaccines as a test of cure, and although by omitting it the number of days under treatment could be reduced in many instances, the relapse rate would very soon counterbalance any gain. At the present time everything possible has to be done to minimize the number of relapses of gonorrhea cases, and this system has been found, in actual practice, to be far in advance of any other; while the number of days under treatment compares favorably with any known figures.

Le Progrès Médical.

September 8, 1917.

Diabetic Polyneuritis.—Pitres and Marchand refer to the demonstration in 1890 by Auché that degeneration of the peupheral nerves was often seen to occur in diabetes mellitus. Such alterations might be encountered in one nerve trunk or a number. The condition might be silent or manifest itself by sensory, motor or trophic phenomena. Among the latter we find shedding of the nails, falling out of the teeth, a peculiar desquamation (ichihyoid) of the skin, zoster-like eruptions, malum perforans pedis and diabetic gangrene not due to arterial obstruction. Among sensory disturbances are obstinate neuralgias, painful spasms, areas of pruritus or analgesia meralgia paresthetica. Among motor disturbances are to be found pareses and paralyses with the reaction of degeneration and abolition of tendon reflexes. It is not to be inferred that these phenomena were not known before 1890, for they were familiar to clinicians long before that epoch; but our real understanding of their nature begins then. Diabetic neuritis, with or without paralysis, begins with lancinating pains and painful spasms, with or without anesthesia of the skin. Diabetic neuritis yields to treatment more readily than most toxic neuritides, and even the severest forms may respond favorably to treatment. Moreover, they do not leave behind the type of sequel seen in

other forms of neuritis. The expression of the disease differs much in accordance with the number of nerves involved. There may be but a single nerve trunk, or even a branch involved—the third nerve, ulnar, external popliteal and circumflex all seem specially predisposed. Dreulafoy once reported 45 cases of involvement of the third cranial nerve. Polyneuritis, on the contrary, is very rare and the authors know only a score of cases. These exhibit the greatest confusion and evidences of type are quite wanting. Of interest are a few cases of cerebral diplegia, brachial diplegia and paraplegia. The last named is partial—may be restricted to the adductors of the thigh and extensors of the legs. The authors report at length the case of a man aged 47 with oethyma and glycosuria. Later there were pain and weakness on the lower limbs which were followed by a certain amount of atrophy. He also exhibited weakness of the arms. The tendon reflexes were abolished and there were many anomalies of sensation. The patient responded in a remarkable degree to treatment; his symptoms all vanished and he was enabled to return to his occupation as driver of an automobile tractor.

September 13, 1917.

The Limits of Asystolia.—Perrin states that this name originated with Beau who applied it to insufficient contraction of the heart, resulting in dilatation and venous engorgement. Asystolia is symptomatic of various conditions of the heart and its diagnosis is made by the presence of a triad of symptoms—arterial hypotension, tachycardia and oliguria. The author objects to this conception as too narrow, although it represents the typical form. But there are atypical forms of asystolia in some of which the tension may be increased instead of diminished, or the pulse slow instead of rapid, or in which polyuria may replace oliguria. In order to bring the atypical cases into a general conception of asystolia it will be necessary to fix definite limits to the latter. If hypertension is present it means simply that the patient has cardiorenal disease. In such cases asystolia lowers the tension below the average. If the latter is say 210, the individual with asystolia would perhaps show a tension of 180. In Bright's disease we often see the association of high tension and asystolia. Similarly "polyuria" complicating the latter would be of lower degree than in the average subject with interstitial nephritis but might reach 1200-1500 c.c.; too small a quantity to denote an absolute polyuria, although considerable in comparison with the oliguria of typical asystolia. In regard to tachycardia this is wanting in mitral stenosis, in which affection there is compensatory slowing. In this association the pulse may not rise above 80, which would be rapid for uncomplicated mitral stenosis. In regard to treatment the indications are the same in all asystolia, whether typical or atypical. Blood should be withdrawn to relieve the right heart and digitalis given until circulatory equilibrium is reached. Hypotensive substances for hypertension are contra-indicated.

Flexion of the Great Toe from Percussion of the Tendo Achillis.—Villaret and Faure-Beaulieu have contributed a third article on the significance of this induced phenomenon in maladies of the sciatic nerve. This has now been recognized as a sign of value, largely because it is unequivocal and its interpretation does not depend on the appreciation of nuances. Moreover, it may be present as the sole symptom and make the diagnosis in equivocal cases. It probably depends on an exaggeration of the idiomuscular contractility which is so much utilized at present on neurological diagnosis.

Gazette Hebdomadaire des Sciences Médicales de Bordeaux.

September 9, 1917.

Simulation of Cerebrospinal Meningitis by Neosalvarsan Poisoning.—Sabrazés has seen two cases of this character, one of which he relates *in extenso*. A boy of 18 was received into the isolation ward of a hospital for contagious diseases with the diagnosis of cerebrospinal meningitis. The tongue was coated and dry, there was stiff neck and both Kernig and Brudzuiski's signs. The patient was in coma vigil interrupted with delirium. There were precocious, persistent red blotches of vasomotor origin and the countenance was red and swollen. The patient exhibited both vomiting and diarrhea. The temperature was subfebrile, with pulse 74. Neurological examination largely negative. The urine was rather scanty, with a trace of albumin and much arobilin. The blood count showed a hyperleucocytosis of 12,000. Blood was sterile to cultures. Rhinopharynx secretions also sterile. Lumbar puncture negative, or noncommittal. There were injected into the spine 10 c.c. of antimeningococcus serum. Venesection practised in an elbow vein gave blood for urea and Wassermann tests. Blood urea was 0.4 gm. per liter. Wassermann positive. As patient was unable to respond to questions, he was examined for recent syphilis. A healed chancre was found under the prepuce. It was learned that two injections of neosalvarsan had been practised by his physician. The first had been well borne. Sixteen hours after the second one had been given there was a violent reaction of headache and vomiting, fever and chills and sweating. The symptoms became progressively worse and on the third day patient developed apathy and delirium, and was referred to the hospital, as above stated, with the diagnosis of cerebrospinal meningitis. The only further medication consisted of adrenalin and camphor oil by injection, with diuretics and milk diet. Next day the patient was much improved and eventually made a good recovery.

Hygiea.

August 16, 1917.

Cholesterin in a Pleural Exudate.—Arnell reports a case of pleurisy in which the exudate was rich in cholesterin. The patient had had pulmonary tuberculosis, with spontaneous pneumothorax, the latter having been responsible for the incidence of the pleurisy. When patient was first seen this exudate had been encapsulated for six years. Even to the naked eye it exhibited brilliant crystalline flakes, which upon microscopic investigation proved to be cholesterin. After each act of paracentesis the content of the latter in the exudate diminished. At its highest it was less than one-half of 1 per cent. Albumin was present to the extent of 5.23 per cent, of which 0.85 per cent was nucleoproteid precipitated by acetic acid. The cell content was very small. The fluid was sterile and actually possessed preservative properties. The clinical course of the malady was chronic and benign. Treatment consisted of repeated tappings and dietetic-hygienic measures. In this case there was evidently a poor mechanism for absorption, with access of material which could form cholesterin. Such cases usually occur in pulmonary tuberculosis.

Physical Signs of a Cavity in a Case of Pulsion Diverticulum of the Esophagus.—Leffler reports the case of an idiopathic dilatation of the esophagus in a woman of 34. The *x*-rays and physical examination revealed the presence of a pulsating diverticle which communicated with the dilated esophagus. This lay in the upper field of the right lung, and was the size of an orange. The communication was opposite the junction of the second rib to the sternum, and regurgitation could be seen to take place on the screen. This double dilatation of the esophagus is very rare. Originally there was stenosis of the esophagus, but in recent years there has been notable improvement in the symptoms of obstruction. There have been repeated attacks of bronchitis with a feeling of exhaustion which led the patient to consult a physician. The latter made a diagnosis of pulmonary consumption and sent her to a hospital for tuberculosis. In this institution the *x*-ray and physical exploration led to the diagnosis of cavitary tuberculosis, but an injection of old tuberculin failed to produce a reaction. Further *x*-ray exploration after the use of bismuth paste and emulsion established the connection of the cavity with the alimentary tract. In the meantime a careful study of the sputum with the antiformin method eliminated the presence of pulmonary tuberculosis.

Book Reviews.

An Index of Differential Diagnosis of Main Symptoms. By Various Writers, Edited by Herbert French, M.A., M.D. Oxon., F.R.C.P. Lond., Physician, Pathologist, and Lecturer, Guy's Hospital; Consulting Physician to the Radium Institute. Second edition. With thirty-seven colored plates and over three hundred illustrations in the text. Price, $10.00 net. New York: William Wood and Company, 1917.

The 912 pages of this book are filled with much valuable information. There is not a symptom which crops up in the daily practice of the physician that is not most carefully described and the various possibilities of explanation are analyzed and discussed. In so doing it is impossible, of course, to avoid a certain dogmatism. The latest proved facts must be given, not theories or minority reports. Thus it may happen that each reader will find something somewhere in the vast bulk of the book at which to cavil, but no reader can help but find the volume as a whole a mine of information, which he can quarry at will or to which he can turn at once for a nugget of knowledge when the case is urgent; and the alphabetical arrangement of the contents facilitates reference exceedingly. The book is well constructed, the binding is good, and the paper is excellent. The illustrations can hardly be too much praised; those of us who do not visualize so readily as some will find here the conditions described also pictured in a graphic manner. For example, the diagnosis of diphtheria—that *bête noir* of so many physicians who hesitate to send in cultures to the Health Department for various reasons—is aided by pictures of sore throats in their natural colors, all varieties of diphtheria, and Vincent's angina. This book should be placed in the revolving bookcase just beside the physician's desk, within easy arm's reach.

Ammunition for Final Drive on Booze. An Up-to-Date Arsenal for Prohibition Speakers. By Rev. Louis Albert Banks, D.D. Price, $1.50. New York and London: Funk & Wagnalls Co., 1917.

A work of this sort can hardly be reviewed, for it is little more than a scrapbook of press agent clippings. It seems strange that a good cause should need boosting by a method which is so freely used to bolster up weak and evil causes. The medical reader will feel no surprise when he notes the absence of any reference to the many advertised quack medicines containing alcohol. Does not the expression "liquor traffic" apply to these goods?

Nutrition and Clinical Dietetics. By Herbert S. Carter, M.A., M. D., Associate in Clinical Medicine, Columbia University, etc.; Paul E. Howe, M.A., Ph.D., Assistant Professor of Biological Chemistry, Columbia University, and Howard H. Mason, A.B., M.D., Instructor in Diseases of Children, Columbia University, etc. Price, $5.50. Philadelphia and New York: Lea & Febiger, 1917.

The four sections of the book are devoted respectively to the physiology of digestion and nutrition, foods, feeding in infancy and childhood and feeding in disease. The subjects are most difficult to handle, for there is a minority antagonism to almost any practical generalization that can be made, and the author of a book on dietetics must therefore be very conservative in all his views. Few writers dare even today to omit the "red meat" bugbear, although this was "shown up" many years ago. Our authors completely ignore the phrase and do not discriminate against beef and mutton in any diet containing animal protein.

The writer of today has to be conservative in regard to vitamines, certain mineral constituents and all other alleged necessary food ingredients which are destitute of calorific or reconstructive values. We find no mention of the fact that the deficiency diseases appear to shade into one another in certain obscure borderline affections, nor of the alleged affinity between plant vitamines and hormones which has led to the use of the former in medicine. We are glad to see Fletcherism taken out of the category of food fads, but this is the work of the Medical Department of the United States Army.

In the section on foods, alcohol is discussed in a non-committal fashion as well befits such a difficult problem. No prejudice is shown against well-known and approved proprietary foods.

The omission of any reference to diet in cancer seems to us unfortunate, for there is now a large literature on this subject with considerable consensus of opinion. We also find no reference to attempts to nourish the body with amino acids and maintain N equilibrium with inorganic nitrogen, which are at least interesting and suggestive.

The proofreading of the book was very superficial and the index leaves much to be desired.

Muskets and Medicine, or Army Life in the Sixties. Personal Experiences in the War Between the States. By Charles B. Johnson, M.D. Price, $1.25. Philadelphia: F. A. Davis Company, 1917.

The author was but seventeen years old when the Civil War began and saw his first fighting in 1863. During this campaign he began to read medicine as a natural result of his duties as hospital steward. His experience made it an easy matter for him to supply interesting and valuable information on military medicine and surgery covering the last two years of the war. He thus had considerable advantage on one hand over the surgeon who did not begin professional studies until after the close of the war; and on the other hand, over the regular army surgeon, who might have felt less free to record his experiences.

Shell Shock and Its Lessons. By G. Elliot Smith, M.A., M.D., F.R.C.P., F.R.S. Anatomy, and T. H. Pear, B.Sc., Lecturer in Experimental Psychology. Price, $1 net. Manchester: University Press; London, New York, Bombay: Longmans, Green & Co., 1917.

The great trouble with the material which has been published on shell shock since the war began is that too little attention is given to its psychological aspects. The present volume attempts to remedy this by a discussion of the psychology of trench warfare. The authors also have very properly laid stress on the investigation of a shock to patient's mental life by psychological analysis, or psychoanalysis, or by any other name you wish to use to describe a process whereby the symptoms of the patient are understood, not merely enumerated. We could wish for more description of cases, but otherwise it is difficult to find any fault with this little volume.

The Practical Medicine Series. Under the General Direction of Charles L. Mix, A.M., M.D., Professor of Physical Diagnosis in the Northwestern Medical School. Volume IV, Gynecology. Edited by Emilius C. Dudley, A.M., M.D., Professor of Gynecology, Northwestern University Medical School; Gynecologist to St. Luke's and Wesley Hospitals, Chicago; and Sydney S. Schochet, M.D., Instructor in Gynecology, Northwestern University Medical School; Adjunct Gynecologist, Wesley Hospital, Chicago. Series 1917.

This book consists of abstracts of articles on gynecological subjects that appeared in medical journals during the year 1916, together with occasional brief editorial comments. Comparatively little material was available from foreign journals, but there was a considerable increase in the number of American contributions of value. In a brief introduction the editors review the trend of effort, and attention is called to certain interesting facts, among which is that the number of new operations for displacements is said to be eighty-one!

While perhaps the majority of the articles abstracted contain something of value, many seem hardly worth the trouble taken to abstract and print them here. There is one, for example, where even the editors feel constrained to add as a footnote: "Oh surgical indications! How many crimes are committed in thy name!" There are numerous typographical errors and evidences of careless proofreading. For example, one sentence on page 24 is absolutely unintelligible. These books are of value in furnishing an epitome of the literature of each year; but their value would be much enhanced if more care were taken to have the book text correspond exactly with that of the author's original article or the abstractor's manuscript.

Society Reports.

SEVENTH CLINICAL CONGRESS OF SURGEONS OF NORTH AMERICA.

Held in Chicago, October 22-26, 1917.

Monday, October 22—First Evening Session

THE PRESIDENT, DR. FREDERICK B. LUND OF BOSTON, IN THE CHAIR.

DR. OCHSNER, Chairman of the Committee on Arrangements, welcomed the distinguished collection of surgeons, especially of military surgeons, and said he considered them the most useful members of the medical profession at this critical time. He spoke of the work of the committee on the standardization of hospitals which had just closed its meeting, and felt sure that the work done by that committee would be an inspiration to every man to work toward the standardization of hospitals in his community. He said the great purpose of the meeting was to become thoroughly familiar with the wonderful work that the Surgeon Generals of the Army, Navy, and Public Health Service were doing. In closing he said: "This body of men can help because it is composed of men who are clean in their work, in their minds, in their morals and in every way, and they can shorten the war and lessen by hundreds of thousands those who will be lost during the war."

Dr. FREDERICK B. LUND stated that about 14,000 medical men had already enlisted and were ready for service and that they need about 8,000 more, but he was sure that medical conscription would not be necessary. He spoke of the wonderful service that had already been rendered by the men in charge of the units in France, and of the other men who had volunteered their services and attached themselves to the British Expeditionary Forces two or three years ago. In conclusion, he laid emphasisis upon the fact that "to the older men among us the war has brought the priceless opportunity of doing something unselfish before we die. To the younger men the Army and Navy give abundant opportunity to be of service and to show their skill if they have any."

Dr. JOHN G. CLARK of Philadelphia was conducted into office as the new president and said it was his pleasure to sit as an auditor for the evening in the assemblage of military surgeons who were devoting their time and attention to military affairs. They stood in the ranks of those who dealt with salvage rather than destruction and had saved more lives by warding off disease than were killed in Napoleon's army. Splendid progress had been made in the matter of life-saving devices that were already in use and many others were promised which would revolutionize medicine and surgery. He was convinced that medicine would come out of the war far richer than when it entered it.

Dr. FRANKLIN HEAD MARTIN, owing to illness, was unable to be present at the meeting to introduce the distinguished representatives of the Army and Navy and the visitors from abroad, so MAJOR EDWARD MARTIN was requested to take his place.

Secretary DANIELS of the Navy said that it was to the physician that the nation turned in time of war with supreme confidence that in preventive measures they could save the lives of the youths who were willing to rally to the standard, and he expressed the thanks of America to the men who were making the great sacrifices to devote their time and their skill to this purpose. He urged that the physicians use their great influence to stamp out venereal disease which was the most destroying evil that touched the American forces.

During the evening a telegram was received from President WOODROW WILSON and read by Dr. Davis: "To the Clinical Congress of Surgeons of North America: My warmest greetings and best wishes. It cheers us all to see thoughtful, patriotic work done in such good spirit. Woodrow Wilson."

Surgeon General GORGAS of the Army said he had contemplated with dread the necessary enlargement of his corps on account of the war, and had expected to have considerable trouble in the management of so many, but everything had gone smoothly. With the nation engaged in the most important war of all history we must acknowledge that it had responded most nobly in all its branches and not swerved away, but he thought the medical profession might claim preeminence so far. It was only fair to point out to their fellow countrymen that they had measured up to the standard of all that could be expected.

Surgeon General WILLIAM C. BRAISTED of the Navy spoke particularly in regard to the National Board of Medical Examiners which had been carrying on its work for two years and reporting from time to time. The quality of the examinations had been recognized everywhere, and it had recently been announced that the Mayo Foundation would receive their licentiates without further requirements. An examination had just been completed with twenty-nine candidates and there was to be another in January.

Surgeon General RUPERT BLUE of the Public Health Service stated that this was the time for the estimation of values and that everything which led to efficiency brought us nearer victory. Therefore, he was happy to announce that the health of the United States was in better condition today than ever before. There had been an awakening of the conscientiousness of the American people regarding the prevention of disease, and the water and food supplies, the inspection of schools, and the control of communicable diseases had all been placed on a good basis. Research had tracked infection to its lair and provided new methods for its control. With the knowledge that we must fight came the realization that these sanitary measures must be followed, and out of this war would come a better, stronger and more enduring national health.

Col. T. H. GOODWIN, R. A. M. C., wished very much that he could adequately express his appreciation of the honor given him in the invitation to be present as a guest of the Congress. "The medical profession of this country and of Great Britain have for many years past been closely united in ties of social and professional friendship." Servants of the Army and Navy of both these countries had for many years met in the spirit of closest amity and comradeship, and it seemed to him if they could do effectual team work in play they could accomplish even more when in earnest. The two nations were in the fight side by side, with a common object, identical ideals, and with the certain expectation of a mutually attained victory in the future—although probably not in the near future. When he came here five or six months ago Great Britain was in straits owing to the scarcity of medical men necessary, and they owed an unending debt of gratitude to America for the way in which she had responded. Since that time 900 medical officers and nearly 500 nurses had gone across to help on the Western Front, where their work would be helpful beyond description. He fully realized the great amount of pain and suffering that had been relieved by these men, and was convinced that "the friendship which has been felt for many years by the medical men of the two nations and by the armies and navies of the two nations will very soon be felt by the people of these two nations and the days of devotion and self-sacrifice for the good of the country will bind us together in a way which could never have happened in the days of prosperity."

Col. C. DIRCLE of the French Medical Corps received a very hearty welcome and said the manifestations of sympathy moved him more because he realized they were meant less for him than for France herself—France whose dauntless courage and indomitable valor we were applauding every day, and in her name he thanked us from the bottom of his heart. Unprepared she had staggered from the blow of Germany which had prepared for forty years, but after the surprise she had gathered all the forces of her energy and then, stronger than ever before, she had intimated to the Kaiser's troops—so proud and sure of living in Paris—France had intimated to them to stop and they have stopped. He spoke of the battle of the Marne where the glory of the French Army under the leadership of its chief, Marshal Joffre, had accomplished so much. He could not describe the treasures of devotion they witnessed; the death of their men had never been a cause of discouragement on the part of those who followed. On the contrary—there had always been many willing to occupy the vacant places. The American Army had now come to the help of France as did the British Army.

He highly approved of everything he had seen in the training camps he had visited and was sure that every physician and surgeon was ready to do his war work when strikes the hour. This was largely due to the personal enthusiasm and activity of Surgeon-General Gorgas who was giving such wonderful encouragement to everyone who worked in his service.

Colonel Sir BERKELEY MOYNIHAN, Consulting Surgeon to the British Army, said that at midnight on August 4, 1914, England—to her lasting honor—declared war against Germany and at eight A. M., August 5, 1914, he became for the tenth successive generation a soldier of his sovereign. From that time until he stepped on board the boat at Liverpool he had practised military surgery, thought of military problems, and lived with military people. There were about 30,000 medical men in England and one-third of them were wearing the uniform of the King and his Army and had seen actual service or foreign service. The Government had the right to take every man of military age and compel him to serve, but compulsion had always been, and he was sure would always be quite unnecessary. The medical profession in every country was that which had undergone the most complete education and had better and closer opportunity for broadening the mind of the individual practitioner, and if the aristocracy of the land did not rally to the flag we could not expect anybody else to do so. Regarding the work of the Army Medical Corps in his center in Leeds, he said that they had a civilian hospital of 480 beds, with a staff of four surgeons and four assistant surgeons. When the territorial system of hospitals was established throughout the country Leeds was chosen as one of the centers and they were asked to supply a military hospital of 521 beds. They agreed to this and the men attached to the hospital staff became by that act officers in the territorial branch of the Army. Of the eight surgeons there were three left at home—himself included, who was often in France, often in London, and occasionally in Leeds. With that disabled staff, with the help of the practitioners in the neighborhood they were running, with an efficiency he would not hesitate to display to the military surgeons of any land, a military hospital of 6,300 beds. The men of the Royal Army Medical Corps were both soldiers and doctors; as soldiers they went into any part of the line from the front trench to the base according to the needs at the moment. Since the war began up to the 25th of August, 1917, they had suffered 1,800 casualties; that is, that number of their men had either been killed or wounded, gased or disabled from further service. The highest distinction any Englishman could gain, in the opinion of his countrymen, was the Victoria Cross, and they had gained more than their share of that coveted distinction. Twice had members of the R.A.M.C. won both the cross and the clasp, indicating that they had been twice recommended for the honor. He paid high tribute to Surgeon-General Gorgas and Major Mayo for their work in connection with the M.R.C. and in preventive medicine. Ninety-eight per cent. of the British soldiers had been voluntarily inoculated against typhoid, with the result that they had had only 292 deaths from that disease and only 6,022 cases altogether, whereas in the South African war they had 57,684 cases with over 8,000 deaths. A far smaller number of cases of typhoid in this enormously large army living under infinitely more difficult circumstances than they had deaths from this disease in the South African war. In Africa, where the disease known as bilharziosis was so prevalent, they had also made wonderful progress. At the beginning of the war, when it was realized that they would have to have an army in Africa, men were sent out to study this disease, with the result that this parasite had been investigated, all of his domestic secrets had been revealed, and rapidly he was being exterminated, with the probability that bilharziosis would be stamped out from the face of the earth. In many other directions they had made very pronounced progress in other parasitic diseases, leaving out of account any description of the surgical advances. He said, in the opinion of those in high places who were best able to judge, the turning point of the war came in November, 1914, on that memorable day after the battle of the Marne when the second battle of Ypres was fought out. The English Army on that occasion was a thin line, when a man could not by reaching out both his arms touch his nearest neighbor. Between that single line and the coast there was nothing in reserve—everything was put in that line. To that line was supplied all the ammunition they had, which would not now be considered enough for a poor morning's work, 150 rounds per man with four machine guns to each battalion. That line for four nights and three days was bombarded unceasingly, not so much with the idea that those men should be killed, but that they should be prevented from having sleep. On the morning of the 11th the Germans made their attack on that poor, thin, miserable line of weary, begrimed, mud-stained, cheerful "Tommies"—and what was the attack? It was made by the best troops that Germany had at her disposal in the early days of the war, and they were magnificent troops of whom any nations in the world could justly be proud. The odds were never less than five to one and sometimes seventeen to one, and their men were so weary that they leaned their heads against the parapet, nodding in their sleep, so weary they could not see anything to hit until it got thirty or forty yards away, and along that line the German dead were found heaped up seven, nine, ten and eleven deep. The attack failed, and that thin line held, and that was all that stood at that moment between civiliation and disaster to the world. Then they were given a little time—time to prepare and to learn the bestial indifference of Germany to what may be termed the rights of men. They had to learn the hideous malignancy of the submarine peril and the submarine morality of the German people. And so the months went on until the challenge was thrown to America and those in America learned of the contempt that Germany had for America and of the hate that she had for America; "but it is a great compliment, the German hate, for her hate is the other side of fear." He begged his hearers never to forget that Germany was a great and formidable nation with an implacable hatred of them of this country, and said we might be sure that in this war, with her reserves which came up fresh at the rate of a million and a quarter every year, she would use against America every dirty device which she could think of. The question which he had been oftenest asked since coming to America was "when is the war going to end?" He believed that America would find, as England had found, that for her the war would begin when every man of military age in the whole country had offered his services and was prepared to surrender his life to his country. When upon the high altar of patriotism Americans had laid their wealth, their lives, their honor and themselves, and when they welcomed home the bodies of some of their most honored dead, and when they saw moving about their streets those who had offered their lives and given their limbs and their health that the great cause might be saved. His great hope in the war was "that now that America and England stand side by side the old, and stupid, and petty, and miserable little differences which never really amounted to anything shall disappear. The war is hell, but there is a hell of suffering and a hell of dishonor. We have walked through the hell of suffering, and our hearts have been seared by it, but we realize that after all the effect of it is purification; but there is a hell of dishonor that would have burnt in the souls of every man of us if in this great test time of the race we had turned aside and been false to the glorious traditions which we have inherited. Some day the sun of righteousness, and justice, and truth, and freedom shall blaze in full heat upon all the peoples of the earth, but that sun has not yet risen. It is still almost night, or at any rate only in the hours that welcome dawn, but already beyond those sodden hills there is the promise of the dawn."

Major GEORGE W. CRILE of Cleveland said that during his service in France he had heard no one express the opinion that the enemy was wavering or starving, that he was short of munitions or no longer fought a hard fight, or that the Imperial power was crumbling. He had talked with many German prisoners, and they were strong and well nourished. On the other hand, he had heard from British soldiers that when the Britain and the Teuton met face to face the Teuton

threw up his hands and surrendered—which showed that the Teuton had, at least, good judgment. He had come to know the British, but knew the French less well; he had seen the Briton in his difficulties, when wounded, and had seen him die, but never had heard a word of complaint; he had seen the Briton as a hero and had seen the same on the part of the French. He could conceive that the British and the French might not win the war, but he knew that their bodies would never be taken away from the line. They might be buried there, but they would never retreat. He paid the highest tribute in his power to the British and the French who had fought the great enemy machine over the crest of the hill. Everyone in France took it that the war would be long; the opinion that the enemy was weakening, or was nearing a collapse, that the morale had broken, and that the war was almost over, he had heard only since he arrived in New York. This showed a new danger, how extensive had been the peace offensive waged against the United States. Germany had all but convinced us that hers had been the empire of peace, that she invented peace, that she would soon build universities to teach peace to all the world. One day we heard the Germans were rising in their might to overthrow militarism, and the next day they subscribed $3,000,000,000 to militarism.

There were now six American hospitals in France serving with the British Expeditionary Forces. These units had taken over hospitals of from 1,600 to 2,000 beds; there were also several hundred men in the field service, ambulance corps and serving in other capacities. These men were under fire frequently and often shook hands with fate; they knew no fear, but stuck to their tasks bravely, and were men of whom we should all be proud. What had the British medical service accomplished in this war? They had kept their army more free from colds, typhoid and infection than the civilian population of Chicago. Their medical organization was so perfect that their transport never failed. The death rate from wounds and infection in the French and British lines had been reduced to an incredible minimum, and a vast army of soldiers had been returned to active service, wearing on their sleeves the insignia of having been wounded. The war machine was a vast mechanism of force, miles in depth and miles in length. It included all that sustained man, all that clothed man, all that pertained to the health of man, and all that gave him the power to maim and kill. It included all the things created through the labors of men and women and children. One part terrorized and killed; the other part reclaimed and replaced—this was the medical part of the war machine. The first part was most complete. In its broadest sense war was a practical application of physiology and chemistry, and the group that would survive would be the group that furnished the most effective science. The first line trenches must now include our scientific laboratories. The demands of surgery at the present moment were felt by everyone; a new set of problems had arisen, and if they were to be solved we must abandon mere personal interests for the time being. Many surgeons must leave their practice and do for the wounded man what had been done for the diseased. The same intense devotion toward the problems of the wounded soldiers would do for the soldier what had been done for the civilian who remained at home. It was a serious mistake to suppose that military surgery was surgery for the unskilled. It demanded a greater versatility and the ability to stand in twelve hour shifts and to meet every problem that arose in kaleidoscopic sequence. Could any man perform these operations and meet these problems better than the wounded soldier deserved? Let us be quite sure that the best men we could have would have the responsibility of performing these operations. During battle the patients came in flocks. If a man was interested in any particular thing and said so the stream was turned on him until he surrendered. More progress had been made in surgery of the chest and abdomen, in the treatment of wounds and infection and hemorrhage by the method of excision, and in the making of splints, in the brief three years of the war than in all time before. This was not a war of men, but of ideas. It probably now cost more than $100,000 to kill a man. When thousands were to be saved, what greater gain could there be than to discover something in the way of preventive medicine that could be applied?

Tuesday, Oct. 23—Second Evening Session.

The Work of the Army Surgeon.—Surgeon General GORGAS merely introduced the general subject of the work of the military surgeon and left the matter of consideration to the other speakers. He said his personal experience in military surgery was *nil;* he had been in service for forty years, but during that time he had been involved only in the Spanish-American war, and since that time military surgery had been practically born over. This war had demonstrated the fact that we would have to add enormously to the procedures that will have to be adopted before victory comes. The whole question turned upon the question of sepsis. The endeavor of the military surgeon should be to get at the wound as quickly as possible and render it free from infection as soon as possible. The principal role of the administrator would be to get the men at the earliest possible time, and with this object in view we should have our hospitals as near the front line as possible, and all our plans would be bent toward this end.

The Work of the Navy Surgeon.—Surgeon General BRAISTED said it was impossible to give a comprehensive idea of what had been done or of the problems and the enormity of the task before us in the time allotted. He called attention to the enormous increase in the number of enlisted men in all departments of the Navy and to the fact that the medical department must also look out for all the men engaged in the construction work for the Navy, which made a total of nearly a half million people for whom the Navy was responsible. There were formerly 394 medical men in the Navy, and there were now 828 in the regular service, either commissioned or awaiting commission, this being the full authoried strength of the corps. The men who had been appointed were obtained through a campaign which was instituted in the class A men of the large medical schools of the country, and the only candidates were those who were certified by their deans to be of high standard. It was impossible to put them through the naval medical school in one class, so courses of instruction were instituted in Philadelphia, New York and San Farncisco, as well as Washington. In addition to the 828 men now ready for active detail there were over 700 in the naval reserve corps. The Navy had twelve hospital units organized under and in conjunction with the Red Cross, and five small naval stations, the majority of which were rendering service. Four of the finest hospital corps training schools in the world were maintained by the Navy, and there were sometimes a thousand men in training. Surgeon General Blue had loaned fifteen of his best men to the inspection service, and all naval stations would be inspected by members of this force. Two ships were now being converted into hospital ships, and one now being constructed would be the finest hospital ship the world had ever seen. It would be built from the keel up as a hospital ship of a type never before contemplated. One of these ships would be available within the next two or three months, and the others were being rushed.

Training Camps for Medical Men.—Col. E. L. MUNSON told of the training camps that had been established for medical officers. There were approximately 500 medical men at the outbreak of the war who were capable of playing the medical game as it should be played. The law authorized seven medical men per thousand, but experience abroad had shown that ten per thousand was better. The corps had been increased until now the doctors and dental surgeons alone outnumbered the whole Army of the United States when it went to war with Spain. The Surgeon General was faced with the problem of training these men and at once secured authority to establish training camps for this purpose. There were now three large camps in the country, one at Fort Benjamin Harrison, Indiana; one at Fort Oglethorpe, Georgia, and one at Fort Riley, Kansas. The training at these camps was at first physical, for the average doctor was in need of vigorous physical training to fit him for the tasks

ahead. He was trained as a soldier until he could go as far as the rest in every way and stand a full day's work beside. He must know how to do everything necessary, for he would have to tell others how to do it when actually in service. Lantern slides and moving pictures were shown demonstrating the life at these Medical Officers Training Camps.

Military Laboratories.—Col. F. F. RUSSELL spoke of the necessity of having well equipped laboratories that could be operated on the same principles that were now carried out only in the larger cities. It was demonstrated some time ago that it was not sufficient to have a post laboratory department, and proper laboratories had been established from time to time with staffs of twenty-six men, or more. In these laboratories they had done the Wassermann and other complement fixation tests since 1909, and had done any kind of laboratory work that could be done with specimens sent through the mail. New laboratories were now to be established at all cantonments and in general hospitals at the Posts throughout the country. The laboratories at the cantonments must be able to carry on the regular laboratory work of a community of from 20,000 to 50,000 people. The greatest difficulty had been to secure supplies and apparatus, but this was now being met, and the principal articles had been delivered at all cantonments and additional supplies would be furnished as rapidly as possible. A great many women laboratory workers had offered their services and would be used as civil service employees as the need arose. Two classes of work would be done, clinical pathology for diagnosis in connection with the camp hospitals and the routine examination for typhoid carriers, hookworm carriers and infectious diseases. It was estimated that a million examinations would be necessary for the hookworm alone. The laboratories would also prepare all the vaccines and serums necessary for all the work done in the cantonments. The complete and cordial cooperation of all the officers in the Army would be necessary to achieve success, and the medial officers could do much to lessen venereal disease if they would devote to it the care they had devoted to less common diseases. Much work had already been done in the new diseases of the war—trench fever, trench jaundice and gas gangrene. Many research institutions had offered their services, and all who had worked under General Gorgas had come to have complete confidence in the future of the medical corps in his charge.

Gunshot Wounds and Their Treatment. — Col. Sir BERKELEY MOYNIHAN of Leeds, England, said that surgeons who were called upon at the outbreak of this war to treat gunshot wounds coming over from France were never likely to forget their experience. They had occasionally met with cases of suppuration, but never in the experience of medical men in our generation had cases of virulent infection like these been met with. By slow degrees it was realized that a new set of circumstances had arisen and a challenge had been thrown down to the profession, which had now been triumphantly if not conclusively encountered. The surgeons were scoffed at and told that they had never learned the lessons that Lister had spent his life in teaching, or having learned them had made haste to forget them. His first duty after returning from his first visit to France was to refresh himself with the works of Lister, and he found that in all his teachings Lister had carefully distinguished between the prophylactic work of antiseptics and their therapeutic value. The whole thing was based upon the knowledge that if we prevented the access of microorganisms to the wounds we showed with a gratifying constancy a blameless healing of the wounds. But Lister clearly distinguished in every one of his writings between that prophylactic virtue of antiseptics and their absence of value when once a septic process had become established in a wound. The original idea of the antiseptic system was the exclusion of all microbes from the wounds and during the operation to avoid the introduction into the wound of material capable of introducing sepsis into it. Then in wounds already septic attempts were made with more or less success to restore the aseptic state. Everywhere throughout his works Lister clearly distinguished between the results he expected to get, and it was no just tribute which was brought against the surgeon when he was told that Lister had lived in vain and that aseptic surgery had fallen grievously to the ground.

Sir Berkeley described the way in which a German rifle bullet traveled and the different types of wounds made by it, and said that while he knew the enemy would use every iniquity that could possibly pay, and every kind of infamy if it paid at the moment to do it, he did not use the explosive bullet because there was no accuracy of aim in that bullet as compared with the bullet he did use. One effect of the greatest importance produced by the bullet as it charged its way heavily and clumsily through the tissues with the terrific momentum of 1,000 meters per second was that it not only tore apart the tissues but killed them by means of its terrific velocity. There was not only a track through the tissue but a dead area around this track. It also drove into the tissues anything with which it came in contact, and if a bone was encountered every fragment became a projectile in itself and was driven into the tissues all around. These bullets had been shown to penetrate not only the body of one man, but of two, or even three, in succession. It was interesting to know that you might take the parts of one man out of the wound of another man through whom the bullet had passed. "A part of the pocketbook of one man may be driven into the side of another, and the golden sovereigns in the hip pocket of one may be removed from the buttock of the man behind him." If the bullet met no impediment in its early flight it settled down, and such a bullet might leave only a clean point of entrance and a slightly larger point of exit, but this kind of wound was rare in this war. During the last two years wounds produced by high explosives and by shrapnel had increased in number. "A gunshot wound depends for its qualities not only upon the missile which is used but upon the man whom it meets. The men in this war have been deprived for such long periods of those customary matutinal immersions that have become a part of the life of every civilized man that his skin has become hard and covered with the mud and clay of the trenches. It is impossible to explain the intimacy of the contact between the soldier and the soil on which he is fighting." Many of their men had been drowned in the mud of shell holes, which were sometimes so large that the largest automobile bus could be concealed in them. When the rain came it washed mud into these craters, sometimes filling them up until they appeared the same as the surrounding mud, and many men had stumbled and fallen into these holes and owing to their heavy packs had been unable to extricate themselves and had been drowned. Flanders was probably the most highly cultivated region in all of France, the soil having been fertilized and refertilized for many years, with the result that the mud was of a particular bacterial malignancy. All the kinds of infection which occur in gunshot wounds were those which came from the fecal bacteria that were found in this soil, the streptococcus and the bacillus of Welch being the most frequent. The men receiving these gunshot wounds were weary almost beyond endurance, were suffering shock, and all the circumstances, both local and constitutional, were in favor of a rapidly spreading infection. Looking at these problems from a surgical point of view, it was evident that there should be brought together at the earliest possible moment after the infliction of the wound the best surgical help that was available in the best surroundings. This meant that we wanted the best surgeons, who are young, at the most advanced point in the service to which it was safe to send them and where they could have all the material surroundings which make for safety in surgery.

The one thought should be to obtain complete closure of the wound at the earliest possible moment, either by primary or secondary closure. Primary closure was applicable to all cases where the wound had not involved a wide or deep destruction of tissues, provided you could have that collaboration of the patient and the operator at the earliest possible moment. This consisted in excising the wound as completely as possible and in one piece in order to avoid the reinfection of the new wound that you are making. Primary

closure of the wound was capable of being carried out in a very large proportion of the cases if the surgeons had the courage to do it, probably in 80 or 90 per cent. of the suitable cases. The principles and ideals for which they strove in badly infected wounds were to bring in larger quantities and on a rising tide the swarm of leucocytes into the wound, and perhaps to increase their activity by vaccine therapy, or to make use of the increased antitryptic power of the blood in very grave infection. The aim was to get rid of the sloughs and of discharge, and inhibit microbic growth, and one must be constantly on guard to prevent the active and passive movements of the limb which carried poisonous bacteria into the blood.

In regard to antiseptics Sir Berkeley said that from a military point of view the Carrel-Dakin method was an extremely difficult one to practice. Many people thought a very large part of the success of the Carrel method was due to the fact that the cases were received early, were placed at once under this careful, rigid technique and were retained for long periods. The great fault of the Carrel method was that if it broke down it failed lamentably. Admirable as this method was in time of peace, it had never taken hold in a wide area in the French Army and in England had rarely been accepted as the method of choice. When every circumstance was in its favor it was almost the perfect method; unless all circumstances were in its favor it failed drastically.

A second method was introduced by Rutherford Morrison and had been used by him for two years. It consisted in the free, mechanical exposure of all parts of the wound, the scraping away of all granulation tissues, the removal of all dead and seriously injured portions and all fragments of bone; then the wound was dried with gauze and "a very thin smear of what Morrison calls by the perfectly hideous name of 'bipp' is applied to all the surfaces." Bipp consisted of one part bismuth, two parts iodoform and one part paraffin. The wound was then stitched up without drainage, immobilized and left for ten days. Those cases did amazingly well, but Sir Berkeley had found by much experience that they did equally well when he "bipps them without bipp." He had since persuaded Morrison to try treating some of his cases without bipp, and had his authority to say that they had done just as well without it as any he had ever treated with it. "With a patient returned from France with a compound fracture, with suppuration beyond anything ever seen in civil life, these cases can be opened up, curetted, the dead bone removed, and in three weeks can be healed completely, and the bone united without any antiseptic whatever having been in contact with the wound either at the time of closure or any other time." He thought it did not make much difference what was done to the wounds provided there was a free, mechanical cleansing and a careful, scrupulous, rigid technique.

In closing Sir Berkeley said: "The question is still very open. The last thing that anyone must do is to imagine that a method for the treatment of wounds has finally, by the immense capacity for research, been found either by Carrel, or by Morrison, or by Browning with his flavine compound, or by anyone else. The one certain thing is that if you get your patient early, if you operate ruthlessly, taking away all dead and contaminated tissues, you will find that you can get an early and a perfect healing of that wound by first inteneion. If you cannot get that early access to your patient and see him only when a definite infection is soundly established in all parts of the wound, then again the essential thing is the free, mechanical exposure and cleansing of all parts of the wound, and having done that you may do such other things as you care to try. One method is as good as another and no method the equal of any, but the two things that have come out from all this exhaustive inquiry and most painstaking care of patients is that the primary essential is freedom from exposure of all parts, thorough cleansing, and from first to last the most absolute immobility that you can impose upon any wound of the parts. It is just as important, or more important to immobilize as firmly and as rigidly as you can a wound of the soft parts of the body as a compound fracture of the bone."

Major George W. Crile said he had found practically all of his preconceptions concerning surgery to be wrong. The missiles produced the most extraordinary wounds, and the thing that surprised him as much as any was that the super-mud acted as a missile in itself. A high explosive shell would dive into the mud and throw it with such tremendous velocity that it actually produced a penetration of the skin, and through that hole a vast amount of mud was often forced—much as in the making of a sausage—producing a very bad type of wound and in some instances death. He reflected the opinion of Sir Berkeley Moynihan that complete wound excision was not an easy thing to accomplish until one had had a great deal of experience, but considered it the proper procedure to follow. The wounds were made very much larger than he had ever expected to make, but the patients did remarkably well after this complete cleansing. Concerning antiseptics, the Lakeside Unit took with it a complete outfit for carrying out the Carrel-Dakin technique and used it now in their base hospital, and had also thrown teams forward into the front area. He had never seen any wounds do better than those in which a perfect and typical Carrel was carried out, but their experience had been practically the same as Sir Berkeley had intimated. If there was plenty of help and if well done the wounds did beautifully, but the treatment must be carried out from beginning to end without a slip. He did not know what conditions would be like in the front area, but the moment one was met with the problems presented there it was absolutely impossible to carry out any complicated technique. It meant you were keeping a long line of patients waiting, and before the day was over you had a large percentage of patients who had gone over from the twelve hour period of contamination into the period of infection. The patient should always be operated upon in the period of contamination, before infection had set in, if possible. When he first heard of "bipp" there were three reasons why he doubted whether it would be good—first, it contained bismuth; second, it contained iodoform, and, third, it contained paraffin. He was surprised to find that the patients did well, but it must be used lightly, first making a safe wound by an early operation, and after the dressing give perfect physiological rest. He had also found that if the other procedures were carried out they did just as well without bipp. In his opinion the ideal antiseptic for war surgery had not been found. The problems presented by the carefully trained soldiers who were following the physiological business of fighting were very different from those presented by the average civilian. In civil life no one would think of attacking a wound in the knee-joint, washing it out with salt solution, and closing it up without drainage, but 70 per cent. of the wounds so treated got on without any trouble at all. In all chest wounds they opened the chest widely, took out foreign bodies and clots, removed the blood, and then sewed up the wound tight without drainage, and it healed without any infection. Gas gangrene had now practically disappeared from the acute casualities, for they had learned that it attacked principally the muscles, and if they were excised there was practically no spreading of the disease. It had been found in the wounded men who lie out in "No Man's Land" for from two to ten days, having had wounds all this time, that the wounds that had done best were the ones that contained maggots. The reason that the soil of Belgium and Flanders contaminated so many of the wounds was because there was devitalized tissue, and as the maggot lived on this tissue itself, if it could destroy the devitalized tissue it did in time what the surgical operation did. He believed it was in the power of General Gorgas to do the greatest task of surgery for our armies if he was able to carry out the plan he had in mind of having our hospitals out near the front. In this way the soldiers could be brought in and cared for at the hands of good surgeons early, and that would amount to more than all the antiseptics that one could muster in all the world.

Symposium on the Antiseptic Treatment of Wounds.—Dr. Edward Martin, Philadelphia, said they had been advised by one member of the profession to take all the antiseptics and throw them into the sea, and

another had advised them to raise a brood of tame maggots to take care of wounds. What Sir Berkeley Moynihan had done most of the profession could not do, and what they were after was what they could do best for the good of the Army. The majority of the profession still believed that there was a germicide that killed the germ, and that was what they were after. They were still searching for the best and least injurious, and now Dakin thought he had found it. He had asked Lee to make a trial of his preparation, and the results had been very good. Drs. Furness and Lee had been detailed to carry on the research. They had selected surgeons with large hospital and industrial plants, and the reports were enthusiastic, with the exception of Boston—and that was in its favor. He urged that we await the outcome of these experiments before throwing away all antiseptics and treating every wound with courage and the knife and nothing else.

Dr. Edward K. Dunham of New York stated that we were chiefly indebted to Dr. H. D. Dakin for our understanding of chlorine antiseptics and their mode of use. Bacteriological studies on antiseptics had shown that, even when apparently perfect contact was attained, all the bacteria present were not equally rapidly killed. The rate of disinfection varied with the nature of the disinfectant and the medium in which it acted. For successful disinfection three conditions must be met: First, contact of antiseptic with infecting organisms; second, time during which this contact is maintained, and, third, adequate mass, or concentration of the antiseptic at the points of contact. There were also three things of prime importance that should be known about an antiseptic before it was chosen as appropriate for a given purpose: The speed, or rate of disinfection; the stability of the substance under the conditions of its use; the permissible concentration. The *speed* of disinfection was enormously influenced by the medium in which the antiseptic acted, but even in identical media there was a wide divergence in the speed with which different antiseptics accomplish disinfection. As to *stability*, there were numerous forms of instability manifested by antiseptics when applied to wounds, but the speaker confined himself to members of the chlorine group, explaining the action of the different members of this group. The germicidal action of chlorine antiseptics was not specific, but incidental to the high reactivity of this group of compounds, and for the best results provision must be made for an adequately frequent renewal of the antiseptic. The *permissible concentration* was governed chiefly by the degree of irritation occasioned by the solutions employed, especially upon the skin and mucous membranes. Chloramine-T was far less irritating than the hypochlorites and could be used in greater concentration. Dichloramine-T occupied an exceptional position. It was so slightly soluble in water that adequate solutions must necessarily be ineffective, but solutions in oil could be used in great concentration, up to 20 per cent. if need be, thus introducing an extraordinary mass of antiseptic at a single application, and this abundant mass could become effective, as experiments had shown.

Dr. W. Edsell Lee of Philadelphia reported on 7,228 cases in which dichloramine-T had been used, many of them war wounds in France. From this clinical experience the conclusions offered in their first report had developed into firm convictions. Their experience had been in accord with many of the surgeons that the chlorine preparations had proven superior to all other antiseptic preparations. However, if used for any length of time they produced marked irritation of the skin, so various modifications were tried, and the best was that suggested by Dakin. The original solution was very unstable and had to be prepared almost daily, and the 4.8 per cent. solution contained so little germicidal agent that it was necessary to have it at all times in contact with the wound. It was necessary to renew the solution every two hours, night and day. Carrel and others had overcome most of these faults by the development of a complicated and beautiful technique, which consumed a great deal of time on the part of the surgeon and nurse and an unusual expense for both apparatus and dressing material. They had made a search for a new antiseptic, and Dr. Dakin had requested them to try out the dichloramine-T. By using oil as a menstruum a large mass could be brought into contact with the infection in such a manner that it was slowly infused into the tissues, and during this period its action was in all respects equal to that of the chloramine compound. This eliminated at the start the necessity for the complicated Carrel technique. The results of these clinical tests had been the realization of Dakin's hopes. Dr. Lee illustrated his talk with lantern slides showing the method of applying the solution and the dressings and emphasized the economy in dressings required. By this means they were able to treat 80 cases an hour at their dispensary clinic, and on some occasions had treated 100. They used less than one-fourth of the gauze formerly used, less than one-tenth of the bandages, and had cut down the time of healing from fourteen days to ten.

Dr. William O'Neill Sherman of Pittsburgh spoke in defense of the Carrel method, and said if the impression was allowed to prevail that antiseptics were of no avail there was no use in going to France. We could simply let them put on a bandage over there and send the boys home. He had spent five months in France and England, and every man over there was infected. Carrel's hospital was eight miles back from the lines, but not a man was infected; there was not a drop of pus. He called attention to the work of Shutro, who had 300 beds in Paris and was using this method with good results. There had been 60,000 amputations in France that were due to infection. Lantern slides of wounds before, during and after treatment by the Carrel method were exhibited to show the splendid results obtained.

(To be continued.)

AMERICAN ELECTRO-THERAPEUTIC ASSOCIATION.

Twenty-seventh Annual Meeting Held at Atlantic City, N. J., September 11, 12, and 13, 1917.

Dr. J. Willard Travell of New York, the President, in the Chair.

Presidential Address: The Influence of the American Electro-Therapeutic Association on Electro-Therapeutic Practice.—Dr. J. Willard Travell of New York delivered this address (see Medical Record, October 13, page 627).

Report of the Committee on Dietetics.—Dr. John W. Torbett of Marlin, Tex., made this report. He said the world war had forced us to consider dietetics more from an economic and also a health standpoint. Food faddists with some good ideas had advertised themselves and their special ability to the laity through that great public educator that the doctor dared not use, the public press. The doctor had not done his share to educate his friends and patrons along this line, often, the writer thought, from fear of being called a faddist or quack. We all knew that many people had headaches, urticaria, and many other unpleasant symptoms from eating certain articles of food, and all acute diseases were treated at once by cleaning out the alimentary tract. Monosaccharide and a few other foods only could be injected into the blood without digestion. Sterile milk and most protein foods would cause a profound reaction if injected under the skin and absorbed into the blood. Crystalloids were absorbed through the healthy bowels, colloids were not, but both might pass through the diseased or broken membrane. A person made sick and sensitized by a certain food one time might thereafter react unpleasantly in different ways to its continued use and not realize the cause. Most food sensitizations could usually be overcome by the careful use of very small amounts of the food, gradually increased, if the food were necessary to maintain normal nutrition. The use of only three or four different kinds of foods embracing the proper amounts of proteins, fats, and carbohydrates changed every two days would often help to discover the toxic food. Some raw fruits or vegetable should be eaten every day for the vitamines necessary to maintain normal nutrition. Pigeons fed rough rice maintained their strength, but if fed on polished rice only soon become unable to fly, showing the nutritional value of the phosphorus pentoxide in the pericarp. The blood should be alkaline and the urine acid, which was so

maintained by the foods, bread, meats, prunes, peanuts, plums, and cranberries, while the alkaline conditions were furnished by all other fruits, vegetables, and milk. Most persons were inclined to be too acid, hence the need for the latter class of foods.

The Value of Physical Measures for the Treatment of Wounds and Traumatic Injuries in the War.—Dr. Wm. Benham Snow, New York, called attention to the fact that in the treatment of wounds abroad during the war, it had gradually been established that electricity, light, and other mechanical measures played a most important part in the treatment of wounds and traumatic injuries, such as sprains and synovitis. The experience of the French and English observers had established the fact that the physical methods, in order to be successfully employed, should be under the management of those who understood the methods of application and not under the dictation of either surgeons or physicians who did not. The writer called attention to the great value of radiant light in the treatment of open wounds, streptococcic and staphylococcic infections, and erysipelas, facts which were not generally realized by the profession. He urged the early use of light following an injury both to promote healing with the hyperemia produced, and also as a prophylactic against infection. The use of the static current, as thoroughly established in the treatment of arthritis arising from trauma and sprains and injuries in the proximity of joints, was earnestly urged. In closing the writer expressly called attention to the importance and duty of the members of this association, who understood the principles of these methods, to endeavor to impress upon the Government the necessity of their establishment in the hospitals in this country and also in the hospitals abroad.

Mechanical Vibration Therapy, Exercise Therapy, and Apparatus.—Dr. Mary L. H. Arnold Snow, New York, said that as the interest of the present war demanded that the medical profession employ every available agent for amelioration, cure, or reconstruction, the committee wished to call attention to the indications for the use of mechanical vibration. These indications were: as a means of diagnosis, to elicit pain, to restore tone, and regulate the rhythm of the heart in high blood pressure, as a tissue exerciser in the treatment of various atrophic conditions, in chronic muscular contractions, coccygodynia and sacroiliac luxation, in nervous headache, for relieving local spinal tenderness, and for the reflex effect in asthmatic conditions. Exercise, passive and active, manual and mechanical, are being used in the after-treatment of many conditions as fibrous ankylosis and arthritis, and in the after-treatment of atrophies.

Report of the Committee on the Cancer Problem.—The committee's report called attention to the attitude of the Cancer Commission which assumed that all tumors of the female breast were significant of malignancy and should be removed when discovered. The committee took exception to this attitude, since many of these tumors were easily removed by physical methods of treatment and since in all cases the *x*-ray should precede operation and should also immediately follow the operation—an all important method which the Cancer Commission had always failed to observe. Attention was called to the fact that the Halsted operation, by removing the normal lymphatic glands in the axilla and beneath the pectoral muscle opened the way to the mediastinum which was otherwise protected. Radium in the treatment of cancer was far less effective than the *x*-ray and useful only as a matter of convenience in exceptional cases. While the *x*-ray was not a specific in the treatment of cancer, it inhibits the growth in all cases and some serious forms of malignancy yielded to that treatment. In epithelioma and giant-celled sarcoma it might be considered practically a specific. Success in the use of the *x*-ray for the treatment of malignancy depends very largely upon the skill and technique of the operator. No judgment as to its efficiency could be based upon its indiscriminate or unscientific employment. It was probable that under a more skilful technique it might be successful in most cases of malignancy, lengthening life in all cases by arresting the progress of growth. Probably no form of treatment required greater skill and familiarity in the matter of dosage and methods of application than the *x*-ray. The committee would disparage the massive dose method as there was here too great an element of danger, even in skilled hands. Attention was called to the fact that the important glands of the body—the liver, kidneys, adrenals, thyroids, and other secreting glands should so far as possible be protected during *x*-ray administrations. Protecting screens were for this purpose a necessity. The use of filters for eliminating the rays which produced dermatitis had made it possible to obtain far better results in the treatment of deeply located malignant growths than formerly. For measurement of *x*-ray dosage the pastilles were disparaged because of the unreliability, and the regulation of dosage by controlling the voltage, amperage, distance, and time of exposure, which was more scientific, was to be preferred. The committee also commended the employment of electrosurgical procedures in selected cases by constant current ionization, desiccation, and thermal coagulation methods.

Some Observations on Blood Pressure.—Dr. John W. Torbett of Marlin, Tex., read this paper. He said the pressure should always be taken carefully and quietly, without any excitement to the patient, using a reliable instrument and the auscultatory method on the bare relaxed arm. The systolic, diastolic, and pulse pressure and the pulse rate all should be taken and recorded. From January to August 9 of this year, 1706 cases of general medical and venereal cases of all stages had been examined by him, and of this number only 7 per cent. had a systolic pressure above 150 mm. of mercury and only 50 per cent. of these showed tube casts, albumin, or pus. Fifty per cent. of these by two or three weeks of baths, diet, purgation, and increased elimination had their pressures reduced to normal. The hot blanket pack, autocondensation, or the electric light cabinet, followed by the alternating hot and cold shower, cold mitten rub, or Scotch douche carefully given, were valuable means of promoting elimination, capillary reaction, and resiliency.

Hypertension, Its Early Recognition and Treatment.—Dr. A. L. Gordon of Burlington, N. J., read this paper. He said that in the study of mortality statistics it was found that while the general death rate had fallen during the past few years, the mortality of those past middle life had increased, due mainly to the degenerative diseases. Hypertension was one of the earliest signs of approaching danger, and if discovered early enough and the patient was properly treated he would be spared years of suffering by premature death. The cause was usually found in faulty habits and manner of living, especially overeating and more particularly of proteins, this causing bacterial activity in the gastrointestinal tract with the formation of toxins. Excessive nervous strain, overwork, pyemia, and poisoning by alcohol or lead might also be important factors. Symptoms of early hypertension were rare and it was very important to make a routine examination of all patients past middle life at regular intervals. Treatment consisted in correction of faulty habits, especially as to eating and use of alcohol, and the proper use of electricity. The hypertension could best be corrected by autocondensation. The liver might be stimulated and caused to perform its function of destroying toxins by the use of the static wave or the slow sinusoidal currents. Constipation might be corrected by the slow sinusoidal current over the abdomen.

The Rational Management of Various Types of Neuritis.—Drs. W. L. Clark and H. Smidt of Philadelphia presented this paper. In the acute form the authors laid great stress on rest, with counterirritation and heat by hot water, the lamp, or diathermy. The diet should be looked after and the bowels kept open. Everything that caused contraction should be avoided. In the subacute variety more energetic measures should be used to remove the infiltration. In this stage the lamp might be used plus galvanism, the high frequency vacuum tube, the brush discharge, the high frequency effleuve, the faradic current, or diathermy. If the wave current was used it should be very mild at first. In chronic neuritis, in addition to the foregoing, hyperemia should be produced by the static wave and the static spark. The faradic sinusoidal was good; also hydrotherapy, the electric cabinet, and baking. General tonic and reconstructive treatment should be used.

The Static Wave Current as an Aid in the Treatment

of Diabetes.—Dr. William A. White of New York read this paper. He said that in diabetes there was a diminished activity of the pancreatic parenchyma probably due to acute or chronic congestion with some infiltration. The liver was in a state of passive congestion to a greater or lesser degree. The general nutrition and metabolism were gravely interfered with in diabetes. The static wave current exerted a marked and favorable effect on tissue metabolism throughout the economy, and by the passage of the current through the tissues of the insulated patient functional activity was increased, associated with restoration of the nutritive and secretory processes.

The Treatment of Lowered Nutrition as Present in Tuberculosis.—Dr. Mary L. H. Arnold Snow of New York called particular attention to the importance of nutrition and made a plea for greater attention to the first, or prebacillary stage of the disease when the presence of bacilli was often unsuspected until the radiogram revealed the result of their action in the mediastinal glands. If laboratory investigations revealed the presence of infection the latter should be removed, and the nutritive index raised with instructions to the patient for strict hygienic and dietetic régime. For a high pulse rate, uncomplicated by valvular lesions, intervertebral vibration in the interscapular region would correct the pulse irregularities. The employment of radiant light and heat and the static wave current, or the d'Arsonval current to correct impaired liver function, and the use of the sinusoidal current for the treatment of constipation were indicated, and wherever mediastinal infection was present the *x*-ray was employed with the routine measure of dosage, or variations to meet indications. When *x*-ray treatments were given, precautions should be taken that the thyroid, adrenals, and heart were properly shielded.

The Formation, Equipment, and Administration of an Electro-Therapeutic Unit for Work Abroad.—Dr. Virgil C. Kinney of Wellsville, N. Y., in presenting this paper stated that the electrotherapeutist and the institutional man with executive ability were just as essential for army work abroad as the army surgeon. The author presented plans for a complete 100-bed unit, including buildings, equipment, and administration. This work was placed under two departments: (1) A department entirely separate from hospital work; this to be in a separate building and free from hospital influence. Here so-called rheumatism or any of its allied conditions, the nervous depressions and melancholias, the high blood pressures, or any toxic conditions might be given an intensive elimination and physical upbuilding. (2) A department occupying a portion of an already existing hospital and working in conjunction with the surgeon. This department should have separate rooms for electrical treatment and bath work, and, in addition, much portable apparatus to enable the therapeutist to give his numerous treatments at the bedside. The buildings were designed with special regard to simplicity of design, comfort, economy in operation, elasticity, and mobility. The whole plan was so comprehensive that the government could well spend some time in going over the work.

Physical Therapeutics in War.—Dr. Joseph Rivière of Paris contributed this paper, which was read by Dr. William Benham Snow of New York. The author asserted that, thanks to physical therapeutics and its benefits, the social waste of war could be reduced to a minimum. As soon as the required surgical measures had been completed the wounded of the war should be turned over the physical therapeutist. Some of the cases treated by the author were: Ankylosis, muscular stiffness, retraction, cicatrices, neuritis, atrophy, paralysis, lesions of the nerves and other conditions for the greater part complicated with arthritic manifestations, and disorders of the nervous system.

A New Test for Incipient Cancer of the Breast.—Dr. G. Betton Massey of Philadelphia described this test (see page 803).

The Static Machine in Humid Weather.—Dr. Frederic de Kraft of New York read this paper. He said the static machine was most reliable and could always be depended upon to produce current if certain conditions received attention. The high potential static charge readily leaked away in the presence of moisture. The following features were important: (1) The insulation within and without the case should be as perfect as possible. (2) The material of both revolving and stationary plates should be a perfect dielectric. (3) The case must be air-tight, and the outside must be kept free from dust and moisture. The best material for use in the interior of the machine to absorb both moisture and nitrous oxide was unslacked rock lime, a half barrel to a machine, placed loosely in boxes well covered with cloth. Fresh lime was required about every six months. (4) The gummy substance deposited on and in the case as a result of the action of ionized air and nitrous oxide was best removed by wiping with a cloth wet with kerosene. With due attention to these points a static machine should never lose its charge and should always be ready for use.

When Neuritis Proved a Wrong Diagnosis.—Dr. A. B. Hirsh of Philadelphia detailed the history of several cases that had been diagnosed as neuritis and which were really not neuritis, but pain reflected from some other source. The conclusions to be drawn from these cases were that the presence of actual neuritis must be differentiated from the reflected forms of neuralgia by careful search for the condition underlying each patient's symptoms, and for such differentiation definite measures were now at hand. Given a more correctly defined diagnosis, the probability of success in the treatment of curable cases was far greater than ever before.

The Effect upon Metabolism of Induced Sinuous Impulses.—Dr. Frederick H. Morse of Boston said the body was a storehouse of potential energy. Every part of the body had a normal rate of vibratory activity, the respiration 18 a minute, the peristalsis of the bowel 14 to 18, of the colon 6 to 8, while the ordinary gait was 80 a minute. In treating a part the author advised synchronizing the normal action of the body cells of that part. The value of stimulation of spinal nerve centers had been emphasized of late in many forms of treatment. We should combine stimulation of nervous tone with exercise of a part at its normal rate. Much systemic disturbance arose from stasis in the colon and weakness of the abdominal muscles—constipation. The treatment recommended as most efficacious in this condition was by a large electrode along the spine and smaller one on the abdomen over the colon, with the spine wave regulated to the normal rate of contraction of the part.

The War-Time Uses of Electricity.—Dr. Frank B. Granger of Boston said the war had served to demonstrate anew the value of physical methods of treatment for the relief of pain, the stimulation of certain types of indolent wounds, the removal of infections, the breaking down of ankylosed tissues, the restoration of atrophied muscles, the hastening of regeneration in degenerated nerves, and the improvement and cure of many functional nerve conditions. He divided the war time uses of physical measures into two heads: (1) The immediate and early convalescent stages; (2) the later or more or less chronic stage, or reconstructive and educational. In the first class relief of pain was obtained by radiant light and heat and in some instances by ionization. The condition known as trench foot was best treated by the galvanic current uninterrupted. Indolent wounds would often yield to ultraviolet radiations. Aviators after an exhausting flight were often invigorated by the high frequency in the form of autocondensation or vacuum electrodes over the entire body. Sprains and contusions were treated by radiant heat or diathermy. After the patient had been discharged from the base hospital and sent to another hospital or a convalescent home a greater variety of modalities and a wider range of treatment might be employed. Stiffened and ankylosed joints might be treated by chlorine ionizations. Neuritis and peripheral nerve paralyses should be treated according to the indication. Indolent ulcers were treated with zinc ionization and then ultraviolet radiations. Adherent scars would often yield to chlorine ionization followed by massage. So-called rheumatism, generally a myositis, was best treated by sodium salicylate ionization. In nerve exhaustion, high frequency, static electricity, and general galvanization or sinusoidalization were of extreme benefit. The returned soldier should be educated to earn a livelihood.

Twelve Cases of Anterior Poliomyelitis of the Epidemic of 1916 Intensively Treated.—Dr. Lucy Osborn Wight of New York told of her experience in treating twelve cases of anterior poliomyelitis after they had been discharged from various New York hospitals. Rational treatment consisted in an attempt to restore all possible power and function to the affected muscles and to restore and improve the invariably disturbed circulation. She said the two most important factors in treatment were warmth and rest. The treatment she had used consisted in radiant light to the spine and affected muscles, and also mechanical vibration to the spine and the affected muscles. After the first three months the static wave current was applied to the spine two or three times a week. Massage and muscle training were employed, the child making voluntary efforts to use the limbs in their normal movements. Twelve cases were reported in detail.

State Medical Licensing Boards.

STATE BOARD EXAMINATION QUESTIONS.

Louisiana State Board of Medical Examiners.

New Orleans, June 7, 8, and 9, 1917.

ANATOMY

1. Name the bones that articulate with the radius.
2. What important structures pass through the jugular foramen?
3. Name the nerves of the tongue. Which ones are sensory and which motor?
4. Give origin and function of the spinal accessory nerve.
5. Give origin and insertion of deltoid; digastric; sternomastoid; tibialis anticus, and latissimus dorsi muscles.
6. What muscles are inserted into the lesser tuberosity of the humerus?
7. Describe briefly the ankle-joint.
8. Name principal branches of the external carotid.
9. Describe briefly the blood supply of the intestines.
10. Name and bound the triangles of the neck.

CHEMISTRY.

1. What are alkaloids? Name a few.
2. What does the presence of nitrites in water indicate?
3. Name an alkaline caustic and give its chemical antidote.
4. What are the properties of urea?
5. How would you detect the presence of lead in drinking water?
6. What elements belong to the group of halogens?
7. Give the formula of (*a*) mercuric chloride; (*b*) mercurous chloride.
8. What is ptyalin?
9. What is hemoglobin? State some of its properties.
10. How does iodine occur in nature; give some of its properties.

PHYSIOLOGY

1. Where, and how, are the nitrogenous foods digested?
2. What factors are concerned in the heart sounds in (*a*) diastole, (*b*) systole?
3. How does the vasomotor system influence the blood supply?
4. What is the function of adipose tissue?
5. What are the functions of the cerebellum?
6. State the functions of the (*a*) anterior nerve roots, (*b*) posterior nerve roots, of the cord?
7. What causes the blood to clot? Describe briefly the process.
8. What is the function of the third cranial nerve, and state what muscles are innervated by it?
9. What is the source of animal heat?
10. What is glycogen?

PATHOLOGY.

1. Explain the difference between secretion and excretion, giving example of each.
2. Give the difference between exudate and transudate, with an example of each.
3. Define atrophy. Give the varieties of atrophy.
4. What is the difference between stock vaccine and autogenous vaccine?
5. Describe a Charcot's joint.
6. Give causes, varieties, and results of abnormal blood pressure.
7. (*a*) Mention at least four varieties of ulceration seen in the gastrointestinal wall; (*b*) describe the gross appearance of an amebic ulcer.
8. Describe the process of repair in an uninfected fracture of the bone.
9. Describe carefully the various steps in the formation of a tuberculous cavity in the lung.
10. Describe the process of primary healing; of secondary healing.

PHYSICAL DIAGNOSIS.

1. State four physical signs present in consolidation of lung tissue.
2. State the physical signs present in acute cardiac dilatation.
3. State the physical signs present in brain tumor.
4. Name the various abnormal respiratory sounds (râles), and indicate the physical conditions giving rise to each.
5. What are the physical signs of pyloric stenosis?

HYGIENE.

6. (*a*) What is pure water? (*b*) How should it be rendered potable when impure?
7. Name and describe briefly the methods of purification of public water supply.
8. (*a*) What is natural immunity; (*b*) acquired immunity. Explain each.
9. Describe the disinfection of a room occupied by a careless consumptive.
10. State briefly the sanitary supervision necessary for the production of pure milk.

ANSWERS.

ANATOMY.

1. *Bones that articulate with the radius*: Humerus, ulna, scaphoid (os naviculare), and semilunar (os lunatum).

2. *Structures that pass through the jugular foramen:* Inferior petrosal sinus; lateral sinus, meningeal branches from the occipital and ascending pharyngeal arteries; and glossopharyngeal, pneumogastric and spinal accessory nerves.

3. *Nerves of the tongue*: Lingual branch of inferior maxillary division of the trigeminal (sensory), chorda tympani (taste), glossopharyngeal (sensory and taste), and hypoglossal (motor).

4. Spinal accessory nerve. *Superficial origin:* From the lateral tract, inferior to the pneumogastric; and from the side of the spinal cord as far down as the sixth cervical nerve. *Deep origin:* From the anterior horn of gray matter of the medulla, and of the spinal cord as far down as the fifth cervical nerve. *Function:* Motor nerve to the sternomastoid and trapezius muscles.

5. Deltoid. *Origin:* Outer third of anterior border and upper surface of clavicle; from outer margin and upper surface of acromion process, and from posterior border of spine of scapula. *Insertion:* Middle of outer side of shaft of humerus.

Digastric. *Origin:* Digastric groove in temporal bone; a depression on inner side of lower jaw near the symphysis. *Insertion:* Central tendon attached to body and great cornu of hyoid bone.

Sternomastoid. *Origin:* Upper and anterior part of manubrium, and from inner third of superior border and anterior surface of clavicle. *Insertion:* Mastoid process of temporal bone and to outer half of superior curved line of occipital bone.

Tibialis anticus. *Origin:* Outer tuberosity and upper two-thirds of external surface of shaft of tibia, interosseous membrane, and fascia. *Insertion:* Lower and under surface of internal cuneiform and base of metatarsal bone of great toe.

Latissimus dorsi. *Origin:* Spinous processes of six lower dorsal vertebræ, posterior layer of lumbar fascia, external lip of crest of ilium, and three or four lower ribs. *Insertion:* Bicipital groove of humerus.

6. The subscapularis is the only muscle inserted into the lesser tuberosity of the humerus.

7. THE ANKLE JOINT "is a ginglymoid articulation formed between the lower extremity and malleolus of the tibia on the inner side, the malleolus of the fibula on the outer side, and the astragalus below. Its ligaments are anterior, posterior, external, and internal lateral. The *anterior tibiotarsal* ligament consists of a broad set of irregular fibers attached above to lower margin of tibia, below to astragalus. The *posterior tibiotarsal* ligament passes transversely between back part of tibia and astragalus. The *internal lateral*, or *deltoid*, has two layers—the superficial triangular, its apex arising from malleolus, its base spread out from before backward to be attached to scaphoid and inferior calcaneoscaphoid ligament, the sustentaculum, and inner side of astragalus; and the deep, a short, round cord passing from internal malleolus to astragalus. The *external lateral ligament* consists of three distinct fasciculi, anterior, middle, and posterior, arising from near summit of external malleolus, and being inserted respectively into the front of astragalus, the outer surface of os calcis, and the back of astragalus.—(Young's *Anatomy*.)

8. *Branches of the external carotid artery*: Superior thyroid, lingual, facial, occipital, posterior auricular, ascending pharyngeal, superficial temporal, and internal maxillary.

9. BLOOD SUPPLY OF THE INTESTINES. *Duodenum:* Pyloric and pancreatico-duodenal (of the hepatic), and inferior pancreatico-duodenal (of superior mesenteric). *Jejunum and ileum:* Branches of the superior mesenteric artery. *Cecum and appendix:* Iliocolic and appendicular arteries. *Colon:* Right colic and middle colic (of superior mesenteric), left colic and sigmoid branches (of inferior mesenteric). *Rectum:* Superior hemorrhoidal (of inferior mesenteric), middle hemorrhoidal (from internal iliac), and inferior hemorrhoidal (from internal pudic artery).

10. The ANTERIOR TRIANGLE OF THE NECK is *bounded:* In *front* by a line from the chin to the sternum; *behind* by the anterior margin of the sternomastoid; *base* is upward, and is formed by the lower border of the body of the lower jaw and a line from the angle of the jaw to the mastoid process. It is *divided* into three smaller triangles (inferior carotid, superior carotid, and submaxillary) by the digastric muscle and the anterior belly of the omohyoid. The *inferior carotid triangle* is bounded, in *front* by the median line of the neck; *behind*, by the anterior margin of the sternomastoid; and *above*, by the anterior belly of the omohyoid. The *superior carotid triangle* is bounded, *behind* by the sternomastoid; *below* by the anterior belly of the omohyoid; and *above* by the posterior belly of the digastric. The *submaxillary triangle* is bounded, *above* by the lower border of the body of the mandible and a line drawn from its angle to the mastoid process; *below*, by the posterior belly of the digastric and the stylohyoid; and *in front*, by the anterior belly of the digastric.

THE POSTERIOR TRIANGLE OF THE NECK is *bounded:* In *front* by the sternomastoid; *behind*, by the anterior margin of the trapezius: and its *base* corresponds to the middle third of the clavicle. It is *divided* into two smaller triangles (the occipital and the subclavian) by the posterior belly of the omohyoid. The *occipital triangle* is bounded in *front*, by the sternomastoid; *behind*, by the trapezius; and *below*, by the omohyoid. The *subclavian triangle* is bounded *above*, by the posterior belly of the omohyoid; *below*, by the clavicle; and *in front*, by the sternomastoid.

CHEMISTRY

1. *Alkaloids* are organic, nitrogenized substances, alkaline in reaction, and capable of combining with acids to form salts in the same way that ammonia does. Examples: Aconitine, atropine, quinine, strychnine, cocaine, morphine.

2. The presence of nitrates in water indicates contamination by organic matter.

3. Potassium hydroxide is an alkaline caustic; the *chemical antidote* is acetic acid (vinegar), or citric acid (lemon juice) or tartaric acid.

4. *Urea* is a crystalline solid, colorless and odorless, neutral in reaction, but basic in character, soluble in equal parts of water; it is decomposed by nitrous acid; it forms definite compounds with acids, and also with some salts and oxides.

5. To a sample of the water add a few drops of ammonium sulphide solution; a dark appearance, which does not clear up on the addition of hydrochloric acid indicates the presence of lead (or copper).

6. The *Halogens* are: Fluorine, chlorine, bromine and iodine.

7. Formula of mercuric chloride is $HgCl_2$; of mercurous chloride, Hg_2Cl_2.

8. *Ptyalin* is an enzyme which exists in the saliva, and is capable of converting starch into maltose in an alkaline medium.

9. *Hemoglobin* is the coloring matter of the blood; it is found in the red corpuscles, and is composed of carbon, hydrogen, oxygen, nitrogen, sulphur and iron; it carries the oxygen from the lungs to the tissues of the body. When pure, it is a crystalline solid, red or purple in color, more or less soluble in water; it dialyzes very slowly.

10. *Iodine* occurs in nature in combination only, in sea water, and the plants and animals which inhabit the sea (in the form of iodides); it also occurs as sodium iodate in combination with sodium nitrate. It is a black, crystalline solid, slightly soluble in water; on being heated it gives off a deep violet vapor; in contact with starch it strikes a blue color; chemically, it is less active than chlorine and bromine, which it resembles.

PHYSIOLOGY.

1. *Nitrogenous foods* are digested in the stomach and in the small intestine. In the stomach, by the action of the pepsin (with the hydrochloric acid), the protein molecules are split up into proteoses and peptones. In the *small intestine*, by the action of the trypsin of the pancreatic juice, a similar action occurs, and the proteoses and peptones are further changed into polypeptides and amino-acids, lysin, tryptophane and ammonium compounds.

2. There are two normal heart sounds which follow in quick succession, and are succeeded by a pause. The first, or systolic, sound is dull and somewhat prolonged, the second, or diastolic, sound is sharper and shorter. The sounds may be expressed by the syllables *lubb—dup*.

The first sound is heard best at the apex beat in the fifth left intercostal space; the second sound is heard best over the second right costal cartilage.

The *causes* producing the *first* sound of the heart are not definitely ascertained; the following are supposed to be causatory factors: (1) The vibration and closure of the auriculo-ventricular valves, (2) the muscular sound produced by the contraction of the ventricles, and (3) the cardiac impulse against the chest wall.

3. "Section of a *vasoconstrictor* nerve, such as the splanchnic, causes a loss of normal arterial tone, and consequently the part supplied by the nerve becomes flushed with blood. Stimulation of the peripheral end causes the vessels to contract and the part to become comparatively pale and bloodless. . . . Section of a *vasodilator* nerve, such as the chorda tympani, produces no effect on the vessels, but stimulation of its peripheral end causes great enlargement of all the arterioles, so that the submaxillary gland and the neighboring parts supplied by the nerve become red and gorged with blood, and the pulse is propagated through to the veins; the circulation through the capillaries may be so rapid that the blood is arterial in color in the veins."—(Halliburton's *Physiology*.)

4. *Function of adipose tissue:* To maintain the heat of the body by preventing its too rapid dissipation; as a protective; as a support for the small blood vessels in the long bones, and to give form and roundness to the body.

5. *Functions of the cerebellum:* Coordination of muscular movement and equilibrium.

6. The *anterior* nerve roots of the spinal cord are mainly motor in function; the *posterior* roots are entirely sensory.

7. When blood is withdrawn from the blood-vessels of the living body, it first becomes viscid, then sets, and is converted into a jelly-like mass. This is due to the formation of fibrin. The jelly contracts forming the clot; and at the same time the serum is squeezed out from the clot. Various circumstances and conditions will

hasten or delay the process of coagulation. In man, the blood generally becomes viscid in from two to three minutes; it forms the jelly-like mass in from five to six minutes; a few minutes later the serum begins to appear, and the whole process is completed in from twenty-four to thirty-six hours. The clot then floats on the serum. The process is thus summed up by Halliburton: In the plasma a proteid substance exists, called Fibrinogen. From the colorless corpuscles a nucleoproteid is shed out, called Prothrombin. By the action of calcium salts prothrombin is converted into fibrin ferment, or Thrombin. Thrombin acts on fibrinogen in such a way that two new substances are formed: one of these is unimportant and remains in solution; the other is important, viz., Fibrin, which entangles the corpuscles, and so forms the clot.

8. The third cranial nerve is a motor nerve to the following muscles of the eye: Levator palpebræ superioris, superior rectus, inferior rectus, internal rectus and inferior oblique.

9. *Heat is produced in the body* by: (1) Muscular action; (2) the action of the glands, chiefly of the liver; (3) the food and drink ingested; (4) the brain; (5) the heart; and (6) the thermogenetic centers in the brain, pons, medulla, and spinal cord.

10. *Glycogen* is animal starch; it is present in the liver, in muscles, blood corpuscles and elsewhere in the body. It is a white amorphous powder, tasteless, soluble in cold water; with a solution of iodine it gives a red-brown color.

PATHOLOGY.

1. *Secretions* are materials separated from the blood by glandular cells, and which serve some further purpose in the animal economy; as milk, gastric juice.

Excretions are materials separated from the blood by cell activity, and discharged from the body, and which are harmful if retained; as urine.

2. An *exudate* is the material (fluid and cellular constituents of the blood) which passes from the blood-vessels to the tissue spaces as the result of inflammation. A *transudate* is somewhat similar, but is not due to inflammation; it may be caused by changes in the blood pressure, or vessel walls. *Exudates* have higher specific gravity, more cells, and more albumin than transudates. An *exudate* is found in inflammation; a *transudate* occurs in edema.

3. *Atrophy* is a decrease in the amount of tissue, owing to a diminution in either the *size* or the *number* of the histological elements of which it is composed. It is attended by loss of weight and impairment of function. There are two varieties: (1) *Simple atrophy*, in which the diminution is in *size*, and (2) *numerical atrophy*, in which the diminution is in the *number* of the cells, etc.

4. A *stock vaccine* is one which is prepared from organisms isolated from previous cases of the disease. An *Autogenous vaccine* is one which is specially prepared for each patient from organisms which have been recently isolated from his own lesion.

5. *Charcot's joint.* "In locomotor ataxia the joints of the lower limb, especially the knee and hip, are sometimes affected with painless swelling and distension with fluid, loosening of the ligaments, and wasting of the ends of the bones. This permits of great mobility of the joint, and the ends of the bones are easily displaced (*pathological dislocation*). If the effusion subsides, the displacement generally becomes permanent by shrinking of the soft tissues, and fibrous or bony ankylosis is apt to take place. Sometimes there is great development of new bone at the margins of the capsule, and this leads to further deformity, and in the more mobile joints may prevent reduction of the displacements."—(Buchanan's *Surgery.*)

6. ABNORMAL BLOOD-PRESSURE.—*Pathological High Blood-Pressure.*—"High pressure *per se* is not a disease but a phenomenon or symptom, which may accompany a great variety of diseased conditions, including diabetes, gout, syphilis, chronic lead poisoning, cardiovascular renal disease, many anomalies of nutrition, etc. *Acute Asphyxia and Acute Anemia* of the brain (medullary centers) will powerfully stimulate the vasomotors, causing contraction of the splanchnic area and a rise in blood-pressure. *Lead Colic* affecting the abdominal vessels is usually associated with high blood-pressure, as is also the early stage of peritonitis. *Pain*, even when slight, as in pinching the skin, usually elevates pressure. Continuous high pressure is seen in certain forms of nephritis. Thus in primary acute Bright's disease and in nephritis secondary to scarlet fever, there is practically always a marked rise in arterial pressure. A rise amounting to more than 50 millimeters Hg. has been observed within 48 hours of the onset of an acute nephritis. Elevated pressure is also found in beginning arteriosclerosis of the first part of the aorta and of the splanchnic vessels."

Pathological Low Pressure.—"A pathological depression in blood-pressure may be caused by the depressing influence of circulating toxins, action either upon the heart, blood-vessels or controlling nervous mechanism or to sudden withdrawal of a large volume of blood from the circulation as in hemorrhage, after *venesection, copious diaphoresis, diarrhea*, or in *shock*. In general it may be said that lowered blood-pressure is of little significance except after hemorrhage or during surgical shock. Here the great and sudden reduction in pressure may be sufficient to immediately endanger life. It is noted that a moderate and progressive falling pressure occurs in most progressive and prolonged fevers, as in typhoid fever. When due to such a cause the depression is rapidly overcome and disappears as convalescence is established. Widespread dilatation of the vessels and consequent lowering of blood-pressure has been noted in the last stages of *arteriosclerosis*. (Krehl.)"—(Faught's *Laboratory Diagnosis.*)

7. *Four varieties of ulceration in the gastrointestinal wall:* Gastric, duodenal, typhoid, and tuberculous. *Amebic ulcer:* "Ameba excites at first a moderate exudative and productive inflammation followed by necrosis. Thus ulcers are formed. The ulcers may be superficial or deep, sometimes extending to the peritoneum; they enlarge by infiltration and necrosis at their edges, so that extensive destruction of the mucous membrane may occur. The amebæ may be present in the connective tissue at the base or sides of the ulcers. Not infrequently, owing to bacterial infection from the intestinal contents, varying degrees of suppurative inflammation may complicate the lesion."—(Delafield and Prudden's *Pathology.*)

8. *Repair of fractures:* "The broken ends of the bone are rough and irregular, and the periosteum is torn more or less, but some portion usually remains as a bridge between the fragments. The soft structures in the neighborhood are lacerated, so that the parts are infiltrated with blood clot, which fills up the spaces between the bone ends. As in repair of any other part, the blood clot in a few hours is infiltrated with leucocytes, whose duty it is to absorb the clot. The connective tissue cells in the surrounding parts proliferate, and the bone undergoes rarefying osteitis, so that the place of the blood clot is taken by granulation tissue. The granulation tissue becomes calcified, and the calcified tissue is ultimately replaced by bone. The periosteum plays a large part in the ossification of the new tissue. It becomes stripped up for some distance, hyperemic, and thickened. Granulation tissue is formed from it, and unites with that which has replaced the blood clot. This mass binds the bone together and forms the provisional or ensheathing callus, which is subsequently ossified by the growth of the periosteal osteoblasts spreading over the mass. The medulla becomes plugged with granulation tissue or internal callus, and this, as well as the granulation tissue lying between the fragments of compact bone, becomes ossified, the bone cells of the compact tissue probably proliferating to take part in the repair."—(*Aids to Surgery.*)

9. *Formation of a tuberculous cavity in the lung:* "The anatomical lesion, the tubercle, first appears as a grayish-white, translucent, semisolid granulation, about the size of a millet-seed, usually deposited in the walls of the bronchioles or around the small blood-vessels. From its presence in these situations it induces a low form of inflammation which ultimately results in its destruction. The tubercles then undergo softening or cheesy necrosis with the formation of cavities and consequent destruction of lung-tissue. The small tubercles may coalesce, forming larger nodules, or diffuse tubercular infiltration."—(Hughes' *Practice of Medicine.*)

10. Healing in an incised wound, if aseptic, and the edges are in apposition, occurs by *first intention.* "Exudation of plasma from the neighboring blood-vessels occurs, and its fibrinogen is converted into fibrin, so gluing the edges of the wound together. Leucocytes are poured out and infiltrate the wound, absorbing any blood clot present. These are followed by fibroblasts (connective-tissue cells), which take their place. New capillaries form by budding out from adjacent ones, and vascularize the new tissue. Fibrous tissue is formed by intercellular exudation from the fibroblasts and so the fiorocicatricial union is complete, for at the same time epithelium is spreading over the narrow surface line."

Healing by granulation or second intention occurs when the edges of the wound have not been brought together. "Exudation of plasma and leucocytes occurs, followed by fibroblasts and budding from the capillaries, thus forming granulation tissue. The dead tissues or sloughs are separated, and a red area of granulation is then exposed. The deeper layer of granulation tissue is converted into fibrocicatricial tissue, which contracts, and so the wound gradually lessens in size. In the meantime epithelium spreads in from the edge over the surface, and so the scar is completed."—(*Aids to Surgery.*)

PHYSICAL DIAGNOSIS.

1. *Four physical signs present in consolidation of lung tissue:* (1) Decreased resonance, on percussion; (2) increased vocal fremitus; (3) bronchial or harsh respiration, and (4) bronchophony.

2. In *acute cardiac dilatation: Inspection* shows diffused and indistinct cardiac impulse, and enlarged and distended superficial veins. *Palpation* shows a feeble and irregular cardiac impulse, and also confirms the signs found on inspection. *Percussion* shows increased cardiac dullness. *Auscultation* shows that the heart sounds are weaker than normal, and the first sound is sharper than usual. If there are any valvular lesions the characteristic murmurs will be heard.

3. *Brain tumors:* "The symptoms common to all cerebral tumors are: Headache, persistent and increasing in intensity; defects of vision, even blindness, due to an optic neuritis, a very constant symptom; defects of hearing, taste, and of speech, the result of paresis of the vocal cords; vertigo, associated with nausea and vomiting and convulsions, epileptiform in character. These convulsions are usually limited to one side of the body and occur at regular intervals. They may be localized (Jacksonian epilepsy) to one or more groups of muscles and are never attended with loss of consciousness. Nystagmus is sometimes present. Palsies such as strabismus, ptosis, dilatation of the pupil, facial palsy, paraplegia, and hemiplegia are not uncommon symptoms. Defects of sensibility such as sensations of numbness and coldness in the limbs and body may also occur. Occasionally, there are disturbances of equilibrium, manifested by a tendency, when standing, to go backward or turn to the right or left. The intellectual faculties may be well preserved until late in the affection when irritability of temper, depression of spirits, impairment of memory, emotional disturbances, and a gradually advancing dementia may develop. Slowing of the pulse, insomnia, and increased secretion of urine sometimes accompany cerebral tumors."—(Hughes' *Practice of Medicine.*)

4. *Abnormal respiratory sounds.*—"*Bronchial breathing* occurs in lobar pneumonia, phthisis, compensatory emphysema, tumor, syphilis, and infarct. Both inspiration and expiration are harsh and have a high-pitched (tubular) character. *Cavernous breathing* is low-pitched and blowing in character and is heard over cavities. *Amphoric breathing* is similar to the sound produced by blowing gently over the mouth of an empty jar. It is present in phthisical cavities, pneumothorax with patulous opening, and localized consolidation near a large bronchus. Adventitious sounds include râles, metallic tinkling, and pleuritic friction sound. Râles may be dry or moist: *Dry râles* occur in bronchitis and asthma, and may be low-pitched snoring sounds (sonorous râles) or high-pitched whistling sounds (sibilant râles). *Moist râles* are produced by the passage of the air through liquid, and may be crepitant, subcrepitant, or gurgling in character. *Crepitant râles* are extremely fine and occur at the end of inspiration; they are heard in the first stage of pneumonia and in engorgement and edema of the lungs. *Subcrepitant râles* are comparatively few in number, and are heard during inspiration and expiration, in capillary bronchitis, pulmonary edema, hypostatic pulmonary congestion, and incipient phthisis. *Gurgling râles* may be large or small, and are heard during inspiration and expiration in phthisical cavities, bronchial hemorrhage, in the stage of secretion in bronchitis, and over the trachea. *Metallic tinkling* is a bell-like sound heard in pneumothorax and phthisical cavities, and is caused by the dropping of a liquid through the space inclosed in tense walls. The *succussion splash* is produced in pneumothorax when the patient is suddenly shaken. *Pleuritic friction sounds* are heard during inspiration and expiration, and do not pass away after coughing. They are pathognomonic of pleurisy."—(*Pocket Cyclopedia of Medicine and Surgery.*)

5. *Physical signs of pyloric stenosis:* There is an abnormal prominence of the epigastric region; a tumor in the region of the pylorus which seems to be connected with the stomach; percussion gives a tympanitic note (if the stomach is empty), extending to or below the umbilicus; if the stomach is full, the note is high pitched; on auscultation, a splashing and rumbling sound is heard.

HYGIENE.

6. *Pure water* is colorless, odorless, cool, without disagreeable or salt or sweetish taste, and is free from bacteria, poisons, foreign bodies, etc. *Potable water* should be colorless, odorless, cool, limpid, soft; it should have an agreeable taste, neither salty nor sweet nor flat; it should dissolve soap readily without formation of a curdy precipitate; it should contain not more than about twenty-five to thirty grains of solids per gallon, and should not be polluted with sewage. Contaminated water is purified by: Distillation boiling, filtration, precipitation, and various chemical processes.

7. *The means of purification of public water supplies* are storage and sedimentation, chemical treatment, and filtration. *Sedimentation.* A part of the impurities in the water may be removed therefrom by storing the water in basins where the suspended matter sinks by the action of gravity, and in the process of settling entangles other impurities, as well as some of the bacteria in the water. In order to get good results, the basins must be shallow, the water left undisturbed, and the accumulated sediment removed from time to time. No complete reliance can be put on this method, as it does not guarantee a germ-free water. *Chemical purification:* The sedimentation of water in the basins may be hastened by the addition to the water of certain chemicals, which act as coagulants and form precipitates, entangling the organic impurities and bacteria, thus freeing the water from a large part of them. Alum (half a grain to the gallon), chlorine, bromine, copper sulphate, metallic iron, and ozone are used for this purpose. Neither sedimentation nor chemical purification are practicable for large water supplies, nor are they free from many objections. *Filtration:* This is the only method which has proved successful in providing a pure water supply. Filtration of large quantities of water is accomplished by means of sand beds of large area, the sides and bottoms of which are concreted, and on the bottom of which are placed numerous perforated and open drains which are to lead off the filtered water into separate special reservoirs. On the bottom of the filter areas, which are usually half or an acre in size, is placed a layer of coarse gravel, upon this a layer of finer gravel, which is then covered by a layer of fine, sharp sand, several feet in thickness, the whole filtering medium being from 4 to 6 feet in thickness. The filter is at first filled from beneath so that all air is driven off, and the filter area is then filled to a level of several feet above the filter bed. A filter of an acre in area may be made to filter two to four millions of gallons of water in twenty-four hours. Such filters act not only mechanically in intercepting all suspended impurities, but the slimy sheet which soon covers the top layer of the sand acts biologically upon the water and destroys a large number of bacteria, so that, it is claimed, the water may be freed from 99 per cent. of its bacteria, provided the rate of

filtration is not too rapid and the top of the sand-layers is scraped off half an inch from the surface from time to time.—(From Price's *Essentials of Hygiene.*)

8. *Immunity* is insusceptibility, or capacity for resistance on the part of the body to disease or, in the more limited sense, to infection or intoxication or their effects. Immunity may be *natural* or *hereditary.* The absolute or relative insusceptibility of turtles and fishes for tetanus, and of the lower animals for syphilis and for scarlatina, are examples of hereditary or natural immunity. On the other hand, immunity may be *acquired.* Acquired immunity may be secured by an attack of the disease from which the individual has recovered—*natural immunization.* Or immunity may be acquired by the introduction into the body of some material which gradually diminishes susceptibility without inducing distinct disease—*artificial immunization.* (Delafield and Prudden.)

9. "The clothing and bedding which are to be disinfected by means of steam should be carefully wrapped in cloths saturated with 1 per cent. carbolic acid solution, placed in a wagon, and taken to the disinfecting station. After the bed has been stripped, all refuse matter, paper, and articles of little value are wrapped in cloths saturated with carbolic acid and burned in a stove or furnace. The floor, doors, windows, furniture, and the walls for a distance of 1½ meters from the floor should be washed with 5 per cent. carbolic acid solution. The walls and ceiling of the room should subsequently be sprayed with 1:1000 bichloride of mercury solution. If the walls are papered, it is advisable to remove carefully the paper before beginning the disinfection. The room is then closed as tightl as possible and disinfected by means of formaldehyde."—(Bergey's *Hygiene.*)

10. *Essentials for the production and preservation of pure dairy milk:* Vaughan's rules are as follows: "(1) The cows should be healthy, and the milk of any animal which seems indisposed should not be mixed with that from the healthy animals. (2) Cows must not be fed upon swill or the refuse from breweries or glucose factories, or upon any other fermented food. (3) Milch cows must not be allowed to drink from stagnant pools, but must have access to fresh, pure water. (4) The pasture must be freed from noxious weeds, and the barn and yard must be kept clean. (5) The udders should be washed and then wiped dry before each milking. (6) The milk must be at once thoroughly cooled. This is best done in the summer by placing the milk can in a tank of cold water or ice water, the water being of the same depth as the milk in the can. It would be well if the water in the tank could be kept flowing, and this will be necessary unless ice water is used. The tank should be thoroughly cleaned each day, to prevent bad odors. The can should remain uncovered during the cooling, and the milk should be gently stirred. The temperature should be reduced to 60° F., or lower, within an hour. The can should remain in cold water till ready for delivery. (7) Milk should be delivered, during the summer, in refrigerated cans or in bottles about which ice is packed during transportation. (8) When received by the consumer, it must be kept in a clean place, and at a temperature some degrees below 60° F."

(*To be concluded.*)

Differentiation of Avian Tuberculosis.—According to Rochaix the bacillus of fowl tuberculosis will liquefy gelose of carrot juice, but not in all cases; hence the test is not dependable for excluding human tuberculosis.—*La Presse Médicale.*

Cephaloplegic Poliomyelitis.—Moreira reported a case of this affection—a type at present seen in Rio short of epidemic incidence. The disease, which has simulated hydrocephalus, is at present regarded as an abortive form of ordinary poliomyelitis. Its relationship to so-called polioencephalitis is not indicated.—*Brazil-Médico.*

Familial Labyrinthine Migraine.—Boenheim refers to three generations—grandmother, mother, and 6 out of 7 grandchildren—which presented so-called horizontal rotatory vertigo (sensation of riding in a merry-go-round) with migraine. The seventh grandchild had the latter uncomplicated. Of 7 great-grandchildren but one has developed the disease, but this defect may be due to tender age.—*Correspondenz-Blatt für Schweizer Aerzte.*

Miscellany.

Sanitary Conditions in Private Schools of New York.—A sanitary survey of the private schools of New York made some years ago showed that many such schools were being conducted under the most insanitary conditions. The Health Department thereon added a section to the Sanitary Code requiring such schools to have permits from the Department of Health. In order to determine whether the regulations with reference to such private schools were being complied with and whether they should be allowed to continue a resurvey has been made. This shows that there are in Greater New York 277 private schools with a registration of 26,334 pupils. Altogether the schools visited contained 1,321 rooms, or slightly over four rooms to a school. In only 36 of these schools were the Health Department rules completely complied with. In 863 of the rooms the floor space provided for each occupant was less than the required 15 sq. ft.; in 51 instances the ventilation was considered inadequate, in 10 the light provided was insufficient, and in seven living rooms were also used as class rooms.

The United States Birth Rate.—The Bureau of Census has issued its initial report on births and infant mortality, which places the statistical method of recording the assets and liabilities of the nation upon a rational foundation. A writer in *American Medicine* has made an analysis of these statistics which shows that the registration area for births comprises the six New England States, New York, Pennsylvania, Minnesota, Michigan, and the District of Columbia. While this is only 10 per cent. of the total area of the United States it contains an estimated population approximately 31 per cent. that of the country. According to the figures of 1915 there was a birth rate of 24.9 per thousand population. The death rate for the same year was 14 per thousand. The figures corroborate others previously presented showing the greater fecundity of white foreign born women over those of native birth. There are, according to these figures, 1,055 male births to each 1,000 female births; the infant mortality of males was 110 as against 89 for females. A comparison of the figures for this area with those of other countries shows that in the United States, in 1915, there were 178 births per 100 deaths; in the Australian Commonwealth (1914) the figure was 267; in Austria (1913) 152; Belgium (1912) 1,081; Italy (1913) 169; the Netherlands (1914) 227; New Zealand (1914) 279; Russia (1909) 152; Sweden (1912) 168. The birth rate in the United States of 24.9 was accompanied by an infant mortality rate of 100, while New Zealand with a birth rate of 26 had an infant mortality rate of 51. The death rate of the United States is not as low as that of the Netherlands, New Zealand, Norway, or Ontario. The United States death rate is exceeded in Belgium, France, Italy, Austria-Hungary, Sweden, Switzerland, and the United Kingdom. It is a matter for congratulation that the statistical method of recording the assets and liabilities of the nation have been placed upon a rational foundation and there is now good reason to expect that the area of registration in this country will be rapidly extended.

AN EPIZOÖTIC OF POLIOMYELITIS AMONG DOGS.

BY HORACE GREELEY, M.D.,
BROOKLYN, N. Y.,
AND
W. L. JOHNSON, D.V.S.,
JAMAICA, N. Y.

PARALYTIC affections of dogs, commonly of sporadic occurrence, have been frequently noted, and the occasional paralysis in connection with canine distemper is well known. But so far as we are aware there have been no reported outbreaks in which the central nervous system lesions corresponded with those observed in human poliomyelitis.

Therefore the small epizoötic which we report is, it is believed, unique in this respect, as the descriptions and photographs show lesions which must be regarded as entirely similar to those found in connection with human poliomyelitis.

In the course of his practice in Jamaica, which, although a part of the greater city of New York, is in all respects similar to a country town of a few thousand inhabitants, Dr. Johnson was called in the early part of March last to see a two-year-old collie dog (the property of a family by the name of Keller) which he found suffering from fever and paraplegia. This dog, after being under observation a week, was chloroformed.

The next case that came under his care was the Gibbs dog, also a collie of like age, and which was affected in the same manner as the Keller dog. This was on April 10. This dog lived for ten weeks.

About April 15 the first Ostrander dog came under observation. This dog was an adult female collie of two and a half years, with a six-months'-old pup. The owner reported that the dog, just previous to the paralysis, had shown some indisposition and a slight cough. When seen, the dog suffered from fever and paraplegia. Two weeks later, when the paralysis appeared to involve partially the left paw, the bladder and bowels, the dog was chloroformed and autopsied.

Two weeks after the death of this last dog her six-months-old puppy developed similar symptoms and, with the consent of the owner, was removed by the authors and kept under close observation. When removed, this dog had a temperature of 102°

FIG. 1.—Microphotograph of a section of cord (lumbar region) of Mollus' dog. Stained with hæmatoxylin and eosin. Magnification 25. (Photograph reduced one-half.)

The description of this and the following sections are so identical with that of a typical human poliomyelitis cord lesion that a quotation of a description of the latter is given to describe the dog-cord lesions:

"*The spinal cord.*—Even with the naked eye a section stained with logwood presents a striking difference from the normal. The gray matter stands out from the surrounding white columns unusually well owing to dense accumulation of nuclear elements within it. Under a low power this appearance is accentuated and, in addition, one is struck by the fact that the anterior spinal artery and its branches and a large number of the chief radial vessels are rendered prominent by the intense cellular infiltration of their walls. This condition obtains with regard to the vessels both in the anterplateral and posterior columns and is often present in the vessels entering with the posterior roots. A more detailed examination shows that most vessels, whether in the white or gray matter, are distended with blood which presents no evidence of ante-mortem coagulation, and that capillary hæmorrhages or red cell extravasations are scattered about. In the gray matter it is noticeable that although the nuclear elements are everywhere in excess of the normal they tend here and there to be gathered together in dense foci which may or may not have any obvious association with vessels. These foci are to be seen in the posterior as well as the anterior horns and are often well marked in the neighborhood of Clarke's column. Even when carefully looked for with higher powers it is difficult to find more than a very few of the anterior horn cells and the majority of these are much changed; they are usually swollen, rounded, and devoid of protoplasmic granules, while their nuclei are often enlarged and excentric. The cells of Clarke's column are similarly affected, although not so completely submerged in surrounding cellular exudation. On the other hand, the white matter is practically free from accumulations of nucleated cells, although the cellular infiltration of the vessel walls is marked, and the neuroglial cell are possibly in some excess. In contradistinction to the gray matter where it is nearly impossible to distinguish the constituent axis cylinders and ganglion cells, in the white matter one is able to detect the usual appearance of axis cylinders and myelin sheaths cut in transverse section, although both axons and sheaths are sometimes swollen, especially in the anterolateral columns. The soft meninges are also the seat of cellular infiltration, generally confined to the anterior median fissure and the anterolateral surface but occasionally on the posterior aspects of the cord as well. The cells lie in the spaces of the connective tissue network, which are consequently enlarged and are more numerous in the neighborhood of vessels."—Quoted from E. F. Buzzard, Goulstonian Lectures, "Certain Acute Infective or Toxic Conditions of the Nervous System—Acute Poliomyelitis," *Lancet*, March 23, 1907.

F., and showed paraplegia and partial involvement of the front leg muscles and paralysis (at lest partial) of bowels and bladder. It had been ill two weeks.

While under observation an attempt was made to introduce, intraspinally, blood serum from another dog, but whenever the needle seemed to reach the spinal canal nothing but a little blood (2-4 c.c.) came out, and as it was feared that a vein and not the canal had been reached no serum was administered in this way. Sixty cubic centimeters was, however, given intravenously without apparent effect. The dog soon began to show great difficulty in eating (it had to be fed milk from a cup), apparently having a partial paralysis of the throat and tongue muscles. It also developed a whining cry which became almost continuous, especially at night. It

FIG. 2.—Portion of section shown in Fig. 1.—Higher magnification (400) of area of anterior horn. (Photograph reduced one-half.) See description under Fig. 1.

was chloroformed after having been under observation fifteen days.

On May 1 a three-year-old collie (the McCormack dog) came under observation. It manifested fever and complete paraplegia. This dog, the owner stated, had never been off his premises except on a leash. The owner's wife said she thought the dog had contracted his disease from her, since she had just previously suffered from a severe pharyngitis, and had fondled the animal a great deal. This dog was nursed for a while and then destroyed.

On May 10 the Robbins dog, a two-year-old mongrel, developed fever and paraplegia, and was chloroformed a few days later.

On May 15 the Molius dog, a four-year-old mongrel, showed the same symptoms, and was likewise chloroformed.

All of the above animals, except the Robbins dog, lived within distances which would have allowed contact, although there was no history of such. Of

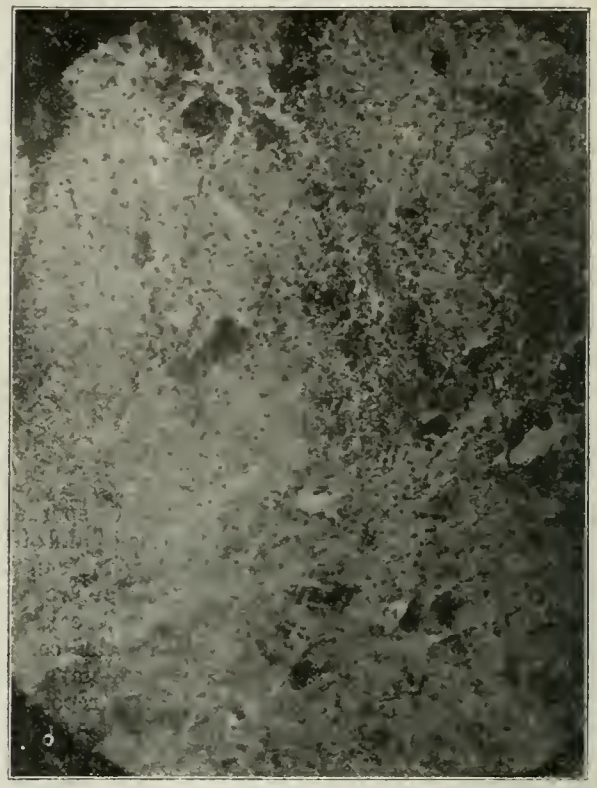

FIG. 3.—Section of upper lumbar cord from first Ostrander dog—region of anterior horn. Stained with hæmatoxylin—eosin, magnification, 400. (Photograph reduced one-half.) Central canal shown to right. The transversely cut blood vessel, and its branch running downward, in upper left hand corner of pictures show particularly well the specific perivascular infiltration

FIG. 4.—Photograph of brain of second Ostrander dog—collie pup—showing congestion of superficial vessels (specimen had been in formalin for some time before it was photographed, and vessels are much less prominent than when fresh).

course, the collie mother and her pup were in intimate contact (in the Ostrander household). In this last family there was an adult male collie, the sire of the pup, that escaped without sign of illness.

The above seven dogs were all that came under

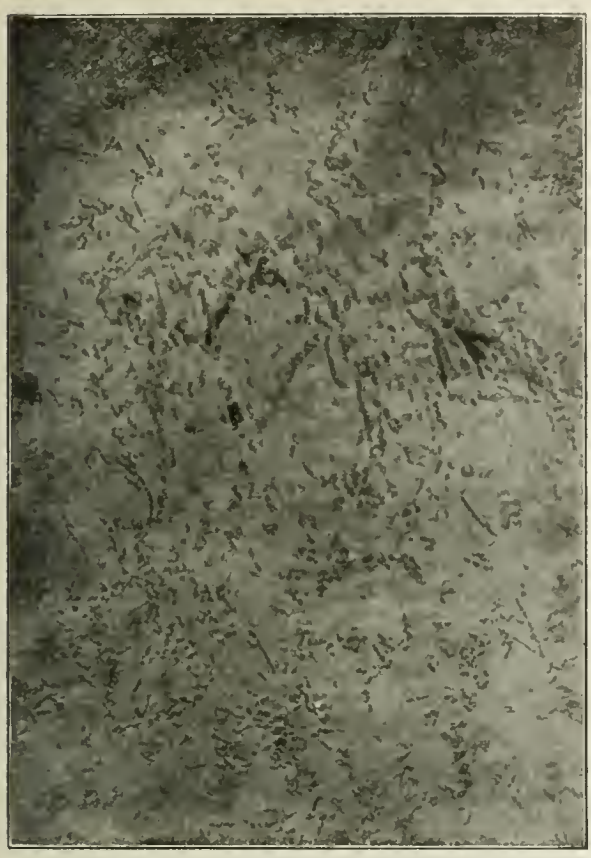

Fig. 5.—Microphotograph of bacillus isolated from brains and cords of dogs; and which was used in inoculation of dog of which a section of spinal cord is shown in the next figure—Fig. 6. Smear stained by Gram's method, counterstained with eosin. Magnification 1500. (Photograph reduced one-half.)

direct observation, but several others, evidently paralyzed, were seen in yards, and still others were reported to be suffering from the condition.*

During the extensive prevalence of poliomyelitis among the human population in this city in 1916, Dr. Johnson did not note any similar cases among the canine pets of Jamaica.

Pathology of Cases.—The first autopsy was performed on the adult Ostrander dog, immediately after the animal was chloroformed, in the Queensboro Hospital by Dr. Abramson. The meninges and superficial vessels of cord and brain appeared congested and the gray matter of the cerebrum softer than normal. Sections of the cord showed perivascular infiltration with leucocytes, which was particularly marked in the gray matter. Some of the nerve cells of the anterior columns could be seen (under high magnification) to be degenerated. (See photomicrographs.)

Autopsy on the puppy of the above showed intense congestion of the superficial vessels of brain and upper cord. Some of the superficial vessels of the cerebrum had given rise to a number of small hemorrhages, while the lumbar cord was purple, evidently from hemorrhagic extravasations which had taken place into its substance. A photograph of the brain of this dog and a microphotograph of a section of the cord from the same are reproduced herewith.

Autopsy on the Molius dog showed slight congestion of superficial vessels of brain and cord. Sections of the cord of this dog showed very markedly the perivascular infiltration and gray matter involvement so typical of human poliomyelitis (see microphotograph).

Bacteriology.—From cords and brains of all three animals a usually Gram-negative, pleomorphic bacillus was isolated—in pure culture from the first and the third. From the second a Gram-positive coccus was also obtained. This latter was later proved not to be what we may call a "fixed" coccus since, on extended cultivation, it developed into the bacillus described. A microphotograph of the pleomorphic bacillus is reproduced herewith.

A young dog inoculated intravenously with 0.25 c.c. of a fluid culture (serum-bouillon-limewater) of the pleomorphic bacillus, repeated on each of four successive days, developed the typical symptoms

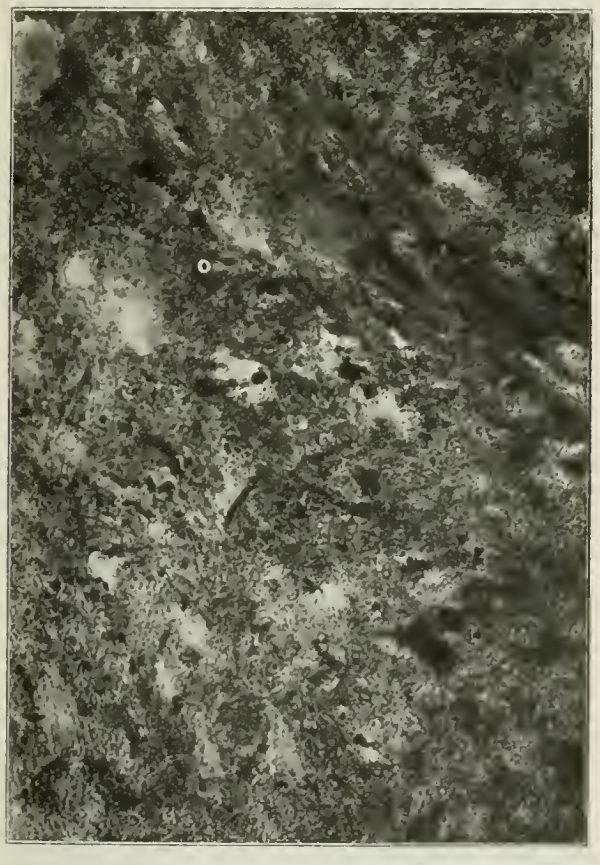

Fig. 6.—Microphotograph of section of cord (region of anterior horn) from dog inoculated with the bacillus isolated from the paralyzed dogs. Stained with hæmatoxylin and eosin. Magnification, 400. (Photograph reduced one-half.)

(paraplegia and fever) and lesions (see microphotograph of section of cord).

The shape of the bacillus varies greatly from a short coccus-like form to a bipolar bacillus. When the poles are well developed they are Gram-positive.

*The number of collies attacked in this series recalls the epidemic, apparently of poliomyelitis, reported among Esquimo dogs, very near relatives of the collies, by Pierson (*J. A. M. A.* Feb. 28, 1914). This may indicate a greater susceptibility of these dogs to the specific paralysis.

The organism is motile and has a single flagellum.

The organism will grow for generations on solidified Loeffler's blood serum, as a Gram-negative pleomorphic bacillus. It, however, tends to develop into a bipolarly Gram-positive bacillus which, when vigorous growth has been attained, will liquefy the solidified serum, at the same time showing as an involuted form from which the polar bodies break out.

It may be grown on plain nutrient agar and in bouillon, but replants from one medium to another often fail.

PARTIAL THYROIDECTOMY.*

AN OPERATION FOR TRANSPLANTING AND ANCHORING THE REMAINING LOBES OF THE THYROID GLAND.

By ERNEST V. HUBBARD, M.A., M.D.,
NEW YORK.

The following detailed account of the technique of an operation for partial thyroidectomy is offered in the hope that better results than those heretofore attained may be achieved from the patient's point of view.

In the removal of the distressing deformity known as goiter it has seemed for some years to the writer that more could be done than to obliterate pressure symptoms and avoid the possible later oncoming exophthalmic goiter.

As will be remarked in the course of the following article, it would seem, among patients who are still young women—and sometimes in older ones, too, deliverance from deformity means almost if not quite as much as lost goiter symptoms. The technique here offered has been given a very considerable, patient trial in some thirty cases. The

Fig. 1.—Case I, one year after operation.

writer will be pardoned for attention to minute, seemingly elementary, details of operation and management, as he is firmly of the opinion that the desired results can be obtained only through strict adherence to the rules laid down.

Granted that an operation is desirable, the following is the method I have employed, with, I trust,

Fig. 2.—Case II, six weeks after operation.

satisfaction to my patients, and I know to myself.

It is preferable for the patient to enter the hospital one or two days before operation. The preparation consists in a soap suds enema the night previous to operation, a second the following morning; diet as usual until the day of operation; no food whatever on this day, and a restricted supply of water.

It is advisable to give the operative area a thorough scrubbing with tincture of green soap washed off with alcohol, a sterile dry dressing being then applied closely to the neck, and allowed to remain untouched until the time of operation, when the surface is painted with a 3 per cent. solution of iodine in alcohol, allowed to dry, and repeated once or twice. Forty-five minutes before entering the operating room, it matters not what form of anesthesia has been chosen, a hypodermatic injection, containing morphine sulphate ¼ grain and atropine sulphate 1/100 grain, limits very considerably the time required to yield to a general or local anesthetic. In young patients from 16 to 20 years, and in frail, lightly built, undersized women, the formula should be halved and is sufficient.

The choice of the anesthetic depends on a number of factors. In patients of high-strung, apprehensive temperament, I believe the use of local anesthetics should be abandoned, as the shock at the time of operation more than counterbalances the greatly diminished postoperative shock and excitement. In patients of a reasonable, self-controlled, quiet disposition, local anesthesia is much preferable to gas-ether or chloroform, and this for two reasons. First, local anesthesia enables the surgeon to talk with his patient while operating, and thus immediately warns him of dangerous interference with the recurrent laryngeal nerve, and

*A thesis presented for election to the American Laryngological, Rhinological, and Otological Society, June 1, 1917.

avoids postoperative vocal cord paresis (nerve bruised), or paralysis (nerve permanently damaged or severed). Secondly, postoperative recovery is amazingly shortened through the use of local anesthesia. Ten days to a fortnight in bed I have fre-

Fig. 3.—Case III before operation.

quently seen reduced to 48 hours. If a local anesthetic is used, cocaine hydrochlorate, 2 per cent. solution, is ample. A towel lightly folded, or soft gauze should be laid across the patient's eyes.

Punctures are made along the line of the proposed incision at intervals of one centimeter, superficially, into the true skin. Sufficient time having elapsed to render the skin insensitive—usually from 10 to 20 minutes—the incision is made. From this time on, during the operation, 1 or 2 per cent. of cocaine is injected deeper and deeper into the tissues. As the operative field becomes painful, I have found that from four to six hypodermatic syringes, containing 30 minims each of a 1 or 2 per cent. solution of cocaine, sufficient for the entire operation. Adrenalin chloride, liberally applied, works admirably to check the milder hemorrhages. It is sometimes convenient to use a solution of 1 per cent. cocaine in adrenalin chloride solution 1 to 1000. Swabbing of the surface with adrenalin, or laying a pledget of surgical cotton moistened with adrenalin for a few moments on the bleeding surface often does very well. Instead of cocaine, and used precisely in the same way, I have had very satisfactory results with a 1 per cent. solution of novocain, or a 1 to 10,000 solution of beta eucaine. These two latter can be used practically ad libitum. I think they are not as reliable in their anesthetic effects as cocaine, but are seemingly harmless.

Reference has been made to conversation with the patient during operation. Far from resenting small talk, patients seem to welcome it, as it keeps the mind more or less diverted, and as I have said, acts as an invaluable danger signal. The onset of quavering or weakening voice is a sufficient warning of impending danger to the laryngeal nerve supply. If there were no other advantages whatever in a local anesthetic, I have found this one acting as a safeguard against accidental nerve severing, as determining its choice wherever feasible.

If a general anesthetic must be used, gas-ether is preferable to chloroform on the same grounds as in other operations, unless there be marked complicating pulmonary or renal disease. The scant margin of safety in chloroform anesthesia applies here as elsewhere, especially if the patient have either true heart disease, tachycardia, or high blood pressure.

Moderate extension of the neck is helpful, using a sandbag or folded sheet under the shoulders.

Formerly a vertical incision at the center of the neck was used. Professor Kocher introduced the crescentic, more or less horizontal incision corresponding with the natural neck creases. The ends of the crescent are cephalad. A good working rule is to place the center of the crescent over the most prominent point of the goiter. The incision should be about one centimeter shorter on each end than the apparent size of the growth. It is obvious that the smaller the incision the less the scar. Enlargement of the field can be had at any time when it is found necessary, continuing the line already made in either direction, and this is best done with blunt scissors curved on the flat. It is well to bear in mind that the apparent and the real size of the goiter are two very different things. One which appears to be as large as an ordinary peach, when the neck is opened may be found double this size, the part felt being superficial, and the larger

Fig. 4.—Case III after operation.

growth extending antero-posteriorly. Subcutaneous tissues are divided with Mayo's scissors until the underlying muscle field is reached. From this point on, anatomical landmarks are very likely to be displaced or obliterated. The surgeon must be guided

by the character of the tissues he encounters. Where a large goiter has for a long period pressed upon the overlying sternohyoid and sternothyroid muscles, I have found them displaced, greatly thinned, and hardly recognizable. The overlying

Fig. 5.—Case IV, six months after operation.

platysma myoides may have disappeared altogether. After the preliminary incision, further separation of tissues should be carried on in a vertical plane. Much can be done with the blunt end of a scalpel, a blunt curved tonsil separator, or perhaps best of all the index finger. The original incision is caused to gape by blunt retractors in the hands of assistants. Milder hemorrhages are controlled with adrenalin as I have indicated, cut arteries are clamped and tied. If one hold to the middle line as far as can be determined, between the sternohyoid muscles, and the separation is kept vertical, danger of severe hemorrhage is practically nil. Having passed the muscle planes, areolar tissue is easily broken through with the finger, and the capsule of the thyroid gland comes into view, of a greyish color. Enlarged veins lying on the capsule must be tied off and severed before opening the capsule vertically.

If the goiter cannot be enucleated through the incision already made, before lengthening the latter, determine whether the sternomastoid on one side or both is not overlapping and binding fast the growth. Often this is the case, and a horizontal nick, one-half to one centimeter long, into the muscle tissue removes the obstruction. Such small muscle incisions do not require suturing.

Some few minutes added to the "operating time," of which many surgeons are so fearful, are more than compensated for by the absence of postoperative hyperthyroidism, directly brought about by over-zealous manipulation of the thyroid gland, with a resulting squeezing out of its contents into the wound and absorption into the general circulation.

One or two fingers are slipped inside the capsule, their palmar surface toward the gland, and are gently coaxed behind the portion to be removed. This is lifted free of the wound, and with some blunt instrument an interlobar separation is effected. A slight cauterization will check any hemorrhage if the separation is made between lobes. The capsule itself, and the goiter as far as possible, should be handled only with mouse-tooth forceps and artery clamps.

Incision is now made vertically through the capsule, and the goiter appears. It is highly important not to damage the capsule, because the thyroid arteries and veins are spread upon it. The accident of tremendous hemorrhage and very probable death can thus be avoided, because the vessels entering the thyroid gland proper are much diminished in size. I have removed many goiters without being obliged to tie a single artery directly entering the goiter.

If in the blunt separation described, a vessel should be torn, it should be tied off before proceeding further. The capsule is to be left in situ. By intracapsular enucleation, the parathyroids lying at the four "corners" of the thyroid, remain unscathed.

The procedure now differs, depending on how much of the thyroid gland is to be removed. Only extreme cases of goiter warrant an entire removal, involving lifelong exhibition of thyroid extract. It is astonishing how small a remnant of thyroid tissue, if functioning, will furnish sufficient secretion to prevent myxedema. In a large majority of cases the removal of the right or left lateral lobe, which ever is the larger, and perhaps the isthmus and pyramidal lobe, is sufficient. When the remaining lobe still bulks large enough to cause further trouble, such a proportion as seems desirable can be cut

Fig. 6—Case V, showing scar following former operation.

away with a sharp scalpel. In every operation for goiter, in view of possible hemorrhage over a broad surface of torn gland tissue, a Paquelin cautery should be at hand for immediate use. A flat tip, heated dull red, lightly brushed across the bleeding

surface, will immediately check the hemorrhage.

The remaining technique of partial removal of the thyroid gland is offered as the writer's contribution to an improved appearance for the patient in later years. While, surgically speaking, a deformed neck is of comparatively small importance, symmetry means much to the average young woman in whom this malady occurs.

The old method, from this point on, has been to check all hemorrhage, close the wound with sutures, finishing the operation, and leaving a considerable mound, flanked by an equally considerable valley in the neck. It is said that these deformities correct themselves in course of time, I have not found this to be the case. Patients object to being saddled with another deformity, an asymmetrical neck, in exchange for the original tumor. This can be avoided wholly, and a pleasing neck contour obtained, by transposing and anchoring the remaining lobe as follows:

Great care must be taken to free from its bed the lobe to be transposed. As above described, the index finger works its way behind the lobe until the

FIG. 7.—Case V, six months after second operation.

latter is entirely separated from the capsule. Any hemorrhage is to be stopped before proceeding further. At this stage a liberal use of hot saline solution is usually very effective in checking hemorrhage. The lobe is now grasped lightly with artery clamps, taking hold somewhat to the rear of the mass on its external side, and rolling it over slightly beyond the mid-vertical line of the neck. A full crescentric needle, threaded with No. 2 chromicized 10-day catgut, is sunk deeply, not less than one centimeter, into the tissue and drawn through. The needle is then passed through the sternomastoid muscle on the side *opposite* the original bed of the lobe to be anchored. Removing the needle, the gut is drawn tight, bringing into closest apposition muscle and gland tissue, and the suture is tied securely. From four to six such sutures are sufficient.

It will be observed that one gives no further consideration to the glad capsule; it has dropped out of sight and need cause no further concern. There should now be a careful scrutiny of the whole operated field, to detect and stop any possible capillary hemorrhage. Hot saline scolution is again desirable, the wound thereafter being gently and thoroughly dried. The success of the anchoring and of the closure of the wound without drainage depends on these latter points. The skin incision is closed by a continuous subcutaneous suture of No. 1 simple catgut, the needle being introduced at half centimeter intervals. Aristol is freely sprinkled, and a gauze dressing with a liberal use of cotton follows. A double spica bandage should be applied tightly for the first 24 hours to keep all the sutures safe from injury due to restlessness. The patient is put to bed without pillows, and sufficient morphine should be given to insure quiet. Such patients deserve the luxury of a quiet ward if possible. Water, hot or cold, a teaspoonful at a time may be given after 6 hours whenever desired. On recovering consciousness, in cases where general anaesthesia has been used, the nurse must see that the patient make no effort to speak, until 24 hours have elapsed. Pain in the throat, due to vibration of the vocal cords is thus avoided. The nurse can ask the patient about her needs.

The day following operation, outer dressings are removed, a corner of the gauze is lifted with forceps, and the wound is exposed for inspection. If there is no puffiness or exudation, the gauze is replaced with a smaller quantity of cotton, and an ordinary neck bandage is applied more loosely. If there be oozing or puffing, and tension indicating a collection of serum within the cavity, it is necessary to insert a drain. For this purpose a small caliber soft rubber catheter, held in a bayonet forceps, is slipped between the lips of the wound, care being taken not to damage the suture, and the tip of the catheter is carried down to the bottom of the cavity, a distance of 4 to 6 centimeters or more. Two or three lateral holes should be cut in the catheter in the usual way. A safety pin through the protruding end of the catheter prevents its possible loss in the interior. The point chosen for the introduction of the catheter through the wound is usually on the side from which the lobe has been removed, and close to the end of the skin incision. Fluff gauze is laid over the catheter end, and the dressing is then to be completed.

Each day the wound should be examined, but remain untouched, unless the above complication presents itself, when drainage should be instituted as described. If one can obtain primary union, avoiding a drain, an added widening of the scar is escaped. If a drain is introduced at any time, it should be removed daily, cleansed, shortened and replaced until further need of it ceases. Left in place too long, it will cause a fibrous-walled sinus, rather permanent in character, which it is difficult to get rid of except by extirpation. Therefore, it is safer to remove the drain too soon than too late, for it can always be replaced if the need arises. Patients are permitted to speak a few words after the first day. On the second day, patients are usually given one pillow, on the fourth or fifth day all dressings are removed permanently in cases of primary union, and sitting upright in bed is allowed. At the end of a week the patient should be out of bed.

The diet during this period, after the first 12 hours, when all effects of anaesthesia have disap-

peared, consists of small quantities of fluids at frequent intervals, gradually returning to full diet as the pain on swallowing subsides.

A temperature of 100° or 101° Fahr. is to be expected for the first one or two days, when the fever should cease. Other symptoms occurring during operation and after, are better considered as complications.

Complications to be borne in mind are those occurring during operation, and those postoperative conditions appearing in a few hours or days.

Sudden death from heart failure may occur. Safety requires that every patient to be operated on for goiter, should have an *x*-ray picture of the neck and upper half of the thoracic cavity, to determine the possible persistence in adult life of a thymus gland. A shadow revealing a persistent thymus is, I believe, absolute contraindication to operation. Sudden death may also occur from uncontrollable hemorrhage and shock. When the goiter is a part of a general Graves' disease, the danger from sudden death during operation is very much greater.

Perforation of the trachea is an unfortunate accident due to strong adhesion between the tracheal rings and the thyroid gland tissue, added to unwarranted vigorous manipulation on the part of the surgeon. It can be avoided when the gland does not separate with moderate traction, by cutting out with blunt scissors, a small nodule from the gland, and leaving the small piece adhering to the trachea. This remaining portion, not larger than an ordinary raspberry, will include the involved portion of the trachea. If by chance, perforation does take place, passage of air, whistling through the wound informs the surgeon of what has happened. Drying of the surrounding surfaces to prevent the entrance of blood should be immediately resorted to. Perforations having a diameter less than a split pea will take care of themselves. In several instances among the writer's cases, such small perforations have spontaneously healed, the patients coughing for a day or two, and occasionally raising a small quantity of pink-stained (blood) sputum. Keeping the patient elevated, head somewhat lower than the feet, is an added precautionary measure in this complication. If the perforation be larger than above described, suturing of the tracheal wound is indicated. This larger damaging of the trachea has fortunately never occurred to me.

Where a goiter of large size has pressed for a long period on the trachea as will have been indicated often by dyspnea and dysphagia previous to operation, collapse of the trachea to a greater or lesser degree may follow the lifting out of the offending gland. This is a rare complication. Minor degrees can take care of themselves, the flattened and partially collapsed trachea will regain its tone and shape in a few days, sufficient air space being present meanwhile for respiration.

Larger degrees of collapse of the trachea causing obstructed breathing require immediate tracheotomy, provision for which should always be at hand. Removal of the tracheotomy tube later, when the tracheal tissues have somewhat regained their tone, follows, and the subsequent treatment of the wound is on the lines laid down above.

Bruising of the recurrent laryngeal nerves will cause either paresis, or, if sufficiently severe, paralysis of the vocal cord of the corresponding side. Above is indicated the method, where local anaesthesia can be employed, of avoiding this accident. There is, however, no cause for alarm where the degree of paresis is mild. For the first few days after operation the voice remains very hoarse and feeble. Gradually its normal tone and strength return, sometimes requiring two or three months. The use of electricity over the damaged nerve has not, in my hands, hastened voice restoration. If a recurrent laryngeal nerve has been unfortunately severed, unless the ends can be recovered and sutured, of course permanent paralysis of the involved vocal cord follows. Patients submitted for examination with a severe postoperative paresis, however, and not expected to recover a well functioning vocal cord, have regain a satisfactory voice in the course of months. It is possible that in these severer pareses, hypodermatic injections of strychnine into the neck may be of service. Sometimes one sees an hysterical aphonia which must be distinguished from the above conditions as a matter of diagnosis; this complication undergoes spontaneous disappearance in a few days.

The symptom-complex known as acute hyperthyroidism, due, as has been stated above, to absorption of an excessive amount of thyroid secretion during operation, is an alarming condition. Profound unrest, jactitation, air hunger, intense nervous excitement, marked dysphagia and thirst, small rapid pulse of high tension, resembling that of severe peritonitis, with 3 to 5 degrees of fever, constitute a complication lasting from 12 to 48 hours or longer, and after a few days death may ensue, with mounting temperature, reminding one of fatal insolation.

On the other hand, lesser degrees of acute hyperthyroidism make a satisfactory recovery, the symptoms entirely disappearing. Morphine for these patients is most helpful in such quantities as are needful to sedate the nervous system. In spite of all precaution there is occasionally a grave postoperative hemorrhage which may fill completely the cavity in the neck, causing bulging and simulating the shape of the neck prior to operation. The indication is obvious. The wound must be reopened and the bleeding points found and stopped. This complication may occur even 24 hours after operation; therefore it is well to keep a sharp watch on the patient's pulse and general condition. If the hemorrhage has gone far enough the resulting shock and collapse are inevitable, and are to be combated by the usual surgical measures. Detected in time, the danger should be avoided. As is readily seen, much depends on having a nurse who is alert.

As time has passed there has come added knowledge of the conditions to be met, together with improved methods in the treatment of complications, as well as in the technique of the operation itself, and the mortality in partial thyroidectomy has proportionately decreased. In the last thirty such operations I have been fortunate, having to record no deaths. It is but fair to add that all of these were simple goiters, exophthalmic goiters being reserved for another paper.

Reference to the accompanying photographs of

a few of the patients who have undergone the operation above described, will give some idea of the cosmetic results.

CASE I.—Miss A., 18 years old, simple goiter, left lobe, size of an orange. For 3 months slowly improving and finally vanishing paresis left vocal cord. Left hospital in 10 days. Photograph 1 year after operation.

CASE II.—Miss B., 25 years old, colored, large goiter the size of a medium grape fruit, left lobe. No postoperative paresis. Uneventful recovery, left hospital on sixth day. Photograph 6 weeks after operation. Seen 4 months subsequently, the wound visible in the photograph had almost entirely disappeared; there is no keloid.

CASE III.—Mrs. C., 45 years old, large, centrally placed goiter, chiefly of the right lobe, which was removed. Recovery uneventful, no complicating symptoms, left hospital in 10 days.

CASE IV.—Miss D., 21 years old, large goiter, right lobe, of several years' duration, interfering with phonation, and causing a hoarse voice. Removal of right lobe. Uneventful recovery, except increased hoarseness for one month. Left hospital in two weeks. When seen six months later, voice was normal. Scar almost invisible.

CASE V.—Mrs. E., 37 years old. Gave history of *seven* attempts to remove the goiter. Fig. 6 shows scar and sinus following previous operations. A medium sized goiter found at operation, neither lateral lobe of the thyroid having been removed previously; left lobe found considerably enlarged and removed. Fibrous walled sinus extirpated. Incision made along the line of the old citatrix, and all fibrous tissue dissected away. Skin surface cut to make a close adjustment when sutured. Uneventful recovery; left hospital in a fortnight. Fig. 7 shows results six months after operation.

My grateful thanks are due to my chief, Dr. Lewis A. Coffin, and the members of the assistant staff of the Manhattan, Eye, Ear and Throat Hospital, for referring many patients to me suffering from goiter, and aiding me with their cooperation and advice.

17 EAST 38TH ST.

RESULTS OF TREATMENT OF TUBERCULOSIS BY MEANS OF A BACILLUS-DESTROYING COMPOUND.

BY V. VON UNRUH, M.D.,

NEW YORK.

FIRST LIEUTENANT M. O. R. C., U. S. ARMY.

FOLLOWING close upon Koch's discovery of the tubercle bacillus many attempts were made to find some method of destroying the bacillus without injuring the somatic cells of the host. At that time relatively little was known of the other forms of tuberculosis, such as joint, kidney, bladder and intestinal types, hence the pulmonary type was chiefly studied and conclusions derived therefrom. An enormous number of drugs intended to act as tuberclecides were exhibited by mouth, but the gastric and general constitutional symptoms were so disturbing that nothing was gained thereby, and in many cases actual harm was done.

In recent years the quest for a "direct agent" has been fairly abandoned except in the fields of organotherapy and direct tuberculin therapy, which have been tilled with rather indifferent success. For these reasons, therefore, the most determined efforts of late have been directed against tuberculosis by increasing the body resistance, the inherent fighting power, to the maximum, and thus helping the body economy to a determined intramural struggle, so to speak, against a desperate and strongly intrenched enemy. Direct attack upon the nidus of infection has been chiefly surgical and has been limited to the relief of advanced cases for the most part, *i.e.* advanced pulmonary, advanced joint, and advanced kidney and intestinal types, the so-called surgical tuberculosis.

Doubtless many cases of incipient tuberculosis have been arrested or even permanently cured by climatic and dietetic regimen, especially where the general body resistance was already good; but it is also more than probable that a much larger number have gone on to fatal issue. The problem in the last analysis resolves itself into the question of how to kill the causative agent, the tubercle bacillus, with the least harm to the patient and in the shortest span of time.

While much has been written about the weapons we must invent and apply to destroy the tubercle bacillus, very little has been said as to those agencies which the bacillus uses to protect itself against onslaught. It is notorious that the body sites, lungs, kidneys, etc., are the favorite habitat of the tubercle bacillus. Is this possibly because of the inaccessibility of these organs to the action of bactericidal substances which might come in from the outer world? *It needs to be emphasized that the tubercle bacillus is an encapsulated organism encased in a lipoid envelope which strongly resists bactericidal and bacteriolytic substances; and, in the main, substances which proved effective in breaking through this fat capsule were, unfortunately, also active enough to destroy adjacent body cells.** With this in view, therefore, the problem becomes highly experimental in the search for that agent which will destroy the enemy without destroying his habitat to any appreciable degree, or at least to make spontaneous regeneration of normal tissue quickly possible after the battle has been won by conservative forces.

To this end a happy combination has seemingly been found in the use of two drugs which we have been employing for the past five years in tuberculosis not only of the pulmonary type, but of all other types as well. The value of this combination lies in its power to bring about a chemical disintegration of the lipoid envelope of the tubercle bacillus and its ultimate destruction. These drugs are echinacea angustifolia and inula helenium, both described in the American Dispensatory. The following epitome identifies the action of each:

Echinacea. In its physiological action, echinacea produces a feeling of intoxication, flashes of heat, headaches of a dull character, dull muscular pains, subnormal pulse and temperature, cold and numb extremities, and increase in the specific gravity of the urine. All these symptoms pass off gradually within a few hours, showing that the drug has no continuing detrimental or toxic effects. Deaths from overdoses, however large, have never occurred.

Therapeutic action. Echinacea produces direct stimulation of the catabolic processes, increase in glandular activity, and increase in the flow of saliva,

*Many of the text-books make no mention of this capsule. Park and Williams, however, in their work on "Pathogenic Microorganisms" (Lea & Febiger, 1914) say, page 389: "The bacilli have a thin capsule, shown in one way by the fact that they appear thicker when stained with fuchsin than with methylene blue."

sweat, and urine. It thus antagonizes all septic processes and facilitates the elimination of toxins from the organism.

Our laboratory researches, conducted for a period of over four years, have shown that echinacea raises the opsonic index, increases the phagocytic power of the leucocytes, and effects a shift to the right and normal in the neutrophiles ("Arneth count"), where a shift to the left had previously obtained. The leucocytes are directly stimulated by echinacea, their activity is increased, the percentage among the different classes of neutrophiles is rendered normal, and phagocytosis is thus raised to its highest protective capacity. Over 500 differential and Arneth counts were made from which the conclusions here set down were derived. Echinacea produces in the blood effects parallel with and similar to those produced by vaccines, without any of the objectionable features of the latter. Hyperleucocytosis and leucopenia are directly improved by echinacea; the proportion of white to red cells is rendered normal, as is the percentage among neutrophiles; and phagocytosis becomes very evident where formerly no sign of it could be detected under the microscope. As many as eight bacilli enclosed within one phagocyte were repeatedly counted, and this in cases where at the beginning of treatment the third class of neutrophiles had been from ten to twenty per cent. less than the second class. By favorably influencing phagocytosis the number of bacilli is also diminished.

Inula.—English and German investigators have for many years studied this drug in its active principle, inulin or helenin. The consensus of opinion among them is that the drug is of more value in treating tuberculosis than creosote preparations, but that it is extremely difficult to extract the active principle and keep it stable in the atmospheric air. A solution of 1:10,000 of helenin will inhibit the growth of a tubercle bacillus culture, the investigators report. The researches were finally abandoned because of the extreme difficulty in maintaining the chemcial stability of this substance. This fact led me to attempt to obtain a fluid preparation which should carry the active principle in a stable form.

In its physiological action, when given in overdoses, inula produces extreme dryness of mouth, pharynx and trachea, increased peristalsis with lumbar pain, much urging to urinate with scant results, nausea, and vertigo.

In therapeutic doses the action of the drug produces a stopping of night sweats, first increases and then decreases cough and expectoration, and *exerts a direct destructive action upon the tubercle bacillus.* This action upon the bacillus is evidenced by dissolution of the lipoid sheath of the bacillus which is gradually lost in consequence of the probable chemical action of inula upon this lipoid sheath; the sheath is dissolved, or disintegrates, and the granules of the bacillus are thus laid open to destruction by the defensive lysins of the body. The chemical action of inula upon the lipoid sheath is as yet not fully understood. We must for the present be satisfied with the fact that such direct action does take place. It remains for some astute chemist to determine the nature of the action of this and other drugs, such as quinine, upon microorganisms.

Laboratory. More than 2,000 sputa were examined microscopically by Dr. T. S. Schlauch and tubercle bacilli were studied both before and after the exhibition of inula. Intravenous or intramuscular administration of this drug proved that great numbers of tubercle bacilli undergo progressive destruction and annihilation. There is at first a steady, more or less speedy, decrease in the number of bacilli in a given sputum. The bacilli swell up, become thick, heavy, and granular and then appear to undergo fragmentation, only part of the lipoid sheath remaining. Finally they disintegrate until mere dots or beads, the well-known "Much's granules," are seen, and these ultimately disappear also. *These fragments or beads do not stain readily; and the usual sporoid forms show no tendency to further proliferation.* The process of destruction of the bacilli is in proportion to the severity or extension of the infection in each case.

The compound of these two drugs is a colloidal fluid preparation, containing no free alcohol, made after the original formula of Von Unruh.* In 3 c.c. of the compound inula represents 1.33 c.c. and echinacea 1.0 c.c. The compound is administered by intravenous or intramuscular injections. Intramuscular injections are given daily into the glutei or infrascapular muscles as frequently as is tolerated, each injection carrying from 3 to 8 c.c. of the compound. Intravenous injections carry from 10 to 30 c.c. of this compound, undiluted, and are given into the veins of the elbow or those of the ankle three times a week.

The compound used in this manner is absolutely non-toxic. Dilutions of the compound, 1:1,000 in distilled water, will inhibit the growth and render sterile cultures of tubercle bacilli. Inoculations of guinea pigs with cultures thus treated proved negative in every case, twenty-five animals having been used.

Reactions from the compound. (*a*) *Immediate:* Upon intravenous injections there is at once an acceleration of the respiratory rate lasting for about five minutes; also an acceleration of the pulse rate by about fifteen beats per minute; and next a rise of temperature of about one-half degree. There is also more or less pronounced flushing of the face extending to scalp and neck, and lasting for about five minutes. After intramuscular injections these symptoms are much less pronounced, though in more susceptible patients they may resemble the phenomena following intravenous injections.

(*b*) *Subsequent reactions:* In all cases intravenous injections of the compound produce increased cough and copious expectoration, which may continue for several hours, whereupon the patient feels unusually free and comfortable.

(*c*) *General untoward reactions:* These have been observed only in cases of profound systemic tuberculous intoxication, cases that are classed as far advanced. The compound will set free toxins, and so must be used with discrimination. The untoward reactions include rise of temperature of more than one degree, and the establishment of characteristic

*It seems no more than just to give full credit to the assistance of Prof. John Uri Lloyd of Cincinnati who has done a vast amount of research upon drug plants for the U. S. Government. Prof. Lloyd has been untiring in his efforts to render the I-E compound pure and stable. Indebtedness to him is hereby acknowledged.

afternoon rises in cases which have been free from these before. Further untoward effects are extreme dryness of the air passages, swelling of lips and forehead, itching and redness of the whole body surface, and most profuse cough and expectoration lasting for hours, followed by extreme exhaustion. Patients manifesting these symptoms should not receive further injections of the compound.

Animal Experiments. In a parasitic disease such as tuberculosis the host himself is not as important a factor in the study of any specific therapeutic agent as is the specific organism itself. If by our therapy this organism is destroyed or eliminated from the body of the host then we have reason to believe that we have a specific agent against that microorganism. We inoculated fifteen guinea pigs with tuberculous sputum, keeping back five others as controls. Of the fifteen animals inoculated fourteen showed the characteristic symptoms of tuberculosis. An arrest of the disease was attained in ten of the fourteen infected animals treated by injections with the compound, the dose varying between 2 and 5 c.c. for each injection. The four remaining animals died. The charts of these experiments are too lengthy to be incorporated herewith, but can be produced. Moreover, any investigator can easily duplicate these results by his experiments.

Number treated: More than two hundred cases of tuberculosis have been treated up to the present time with this compound. Of this number 150 were treated by us, the rest by other physicians in all parts of the United States. Of four glandular cases two were arrested. while two showed no improvement. In incipient pulmonary cases 100 per cent. of recoveries was obtained. Some of these required only from two to four weeks of treatment, while in others it was necessary to continue treatment for two to four months before arrest of the disease was accomplished. Of moderately advanced cases about 50 per cent. were arrested when their general intoxication was not too profound. Profoundly intoxicated cases and far advanced cases did not yield any results by this method.

Complications: Many pulmonary cases were complicated by lupus erythematosus, involvement of the genitourinary tract, influenza, etc. Some cases showing rapid or widespread progress, or those with constant and grave dyspnea were benefited, while in others of this type no improvement was observed. Far advanced cases with a continuous fever will not be improved by this method.

Time required: In cases deemed curable by present-day methods, arrests of the disease have been obtained by us in from four weeks to eighteen months. With a few exceptions these cases were ambulatory; they were not held to a special diet. Several of our cases had previously been treated by other methods without result. Some of these showed improvement and arrest after treatment with the compound, while others were not benefited.

Effect of the Compound Upon Symptoms and Signs. Night sweats, in the majority of cases, were controlled with comparative ease. In cases where the injections did not stop the sweats we have given the specific inula in fifteen drop doses by mouth, four to six times a day. In particularly obstinate cases of night sweats neither this nor any other of the usual remedies were of any avail.

Hemoptyses appear to be favorably influenced by the compound. Of our cases sixty-five had had hemorrhages before treatment; only three of these suffered further hemorrhages, in the other sixty-two no further hemorrhages occurred.

The cough is at first increased after injections, but within a week or two both cough and expectoration are materially diminished, and the sputum begins to show a distinct watery consistency where before treatment it had been tenacious and mucopurulent. In ordinary cases the cough is reduced to a minimum within two or three months, excessive expectoration occurring in the morning only.

In *joint and bone cases,* either with or without sinuses, the compound was applied in full strength locally. The result was a gradual healing of the sinus, leaving the joint unimpaired where its structural elements had not been destroyed. Out of four such open cases three went on to complete recovery, while the fourth proved beyond help. Over tuberculous joints without an open sinus, local applications of the compound were made, keeping the area well moistened; the result was a restoration of motion, decrease of swelling, and complete recovery of the joint. In all such cases intravenous or intramuscular injections were made at the same time.

Kidney, bladder, and testicle cases: Of such we have treated three, and other physicians report two cases. One of our cases had involvement of kidney, bladder, and testicle; the two others showed only bladder involvement. In these cases urethral and afterwards bladder irrigations were given with the diluted compound, 1 part to 3 parts of distilled water, and at the same time intravenous or intramuscular injections were administered. Of these five cases four went on to recovery, the fifth died. Cystoscopic examinations and cultures from the sediment established the existence of tubercle bacilli in each case before beginning treatment.

Acute cases: We have treated eight acute cases. In these the outbreak of acute pulmonary tuberculosis followed immediately upon attacks of bronchopneumonia. Here we obtained quick results, because the lesions were of quite recent development and the patients were not profoundly intoxicated. The action of the compound in this group was most gratifying. Of these eight cases seven went on to full recovery, the eighth patient died. In one case the compound was given for only seven weeks, resulting in complete clearing up of the lung. In the other cases treatment was continued for from three to nine months with resultant arrest of the tuberculous process. All these cases have been reexamined one, three, and four years after clinical arrest, but no relapse has taken place in them nor have any further untoward symptoms been observed.

It is not thought desirable to lengthen this paper unduly by a number of case reports; these will be made the subject of a future paper and will give all details. However, in order to show what can be accomplished with this method of treatment, we submit an abbreviated report of one rather remarkable case.

S. A. (first case). Female, Denmark, aged 21. March 12, 1912. Family history: mother died of pulmonary tuberculosis. Previous illness: bronchopneumonia at age of eight; ever-recurring attacks of bronchitis thereafter. History: At the age of ten the right

femoral lymph glands broke down; the glands of the left lower extremity followed the same course. At the age of fourteen the superficial and deep cervical glands on both sides became involved, broke down, and continued to suppurate for over four years. Cough and

Fig. 1.—Case 79. Female. Age 40. First examined April 4, 1915. Pleuritic adhesions in right midaxillary line, following two attacks of pleuro-pneumonia in 1910 and again in 1914. Dulness and rales over both apices and both upper lobes down to the level of the nipple. Sputum shows many tubercle bacilli. Both plates by the Knickerbocker Hospital. The plate taken April 12, 1915, shows many infiltrated areas in the apices and upper lobes of both lungs, also a few calcareous foci. Treatment with the compound begun.

expectoration was present at all times. The glands healed very slowly. At the age of sixteen, in 1907, she came to the United States. There was, at that time, and is now, scar tissue over the previously affected glands *in all regions* of the body. At the age of

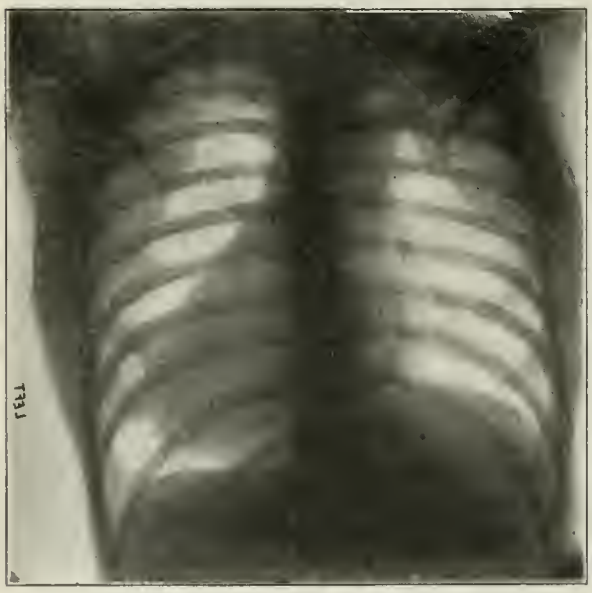

Fig. 2.—Case 79. Plate taken Sept. 21, 1915, shows both lungs fairly clear with a few additional calcareous foci. The sputum continued negative for tubercle bacilli upon repeated examination extending over a period of three months after dismissal.

twenty, in 1911, the cervical glands of both sides again became active; several of these are still open (March, 1912). At this time her right knee joint became involved, with complete loss of motion. She then went to dispensaries and clinics in this city, and finally to one of the hospitals. There she was given about sixty tuberculin injections. This was during the fall and winter of 1911-12. At the hospital her right lower extremity was put in a plaster cast, about February 25, 1912; the cast extended from just above the ankle to

Fig. 3.—Case 16. Male, age 26. First examined Nov. 8, 1913. Both lungs extensively involved, especially the left. Dulness and a few fine, crackling rales at both apices and over both upper lobes. Sputum positive for tubercle bacillus. Both plates by the late Dr. Edward Leaming, Roosevelt Hospital. The plate taken Nov. 12, 1913, shows extensive infiltration of both lungs, especially in the upper lobes. Treatment with the specific compound begun.

Fig. 4.—Case 16. Plate taken Oct. 31, 1914, shows clearing up of both lungs in a little less than one year. The peribronchial glands have undergone calcification. Sputum negative for the tubercle bacillus after repeated examinations. Patient alive and well May, 1917.

the middle of the thigh. No improvement had followed upon the tuberculin treatment. She was first seen by me on March 12, 1912. Treatment: Previous treatment of various kinds having proved unavailing, it was then decided to try the compound by injections. Her symp-

toms at the first examination were as follows: pulse, 108; temperature, 102 ; respirations, 24; night sweats present almost every night; scrofulous appearance; clubbed finger tips; constipation; scar tissue over previously suppurated glands; enormously enlarged anterior and posterior auricular glands of the right side, the posterior ones open and discharging. Smear from these showed tubercle bacilli. Right apex, dulness and moist crackling rales; cough and expectoration; sputum shows tubercle bacilli. Removing the plaster cast, the right knee was found immobile; its circumference was 6 inches larger than the sound left knee. Injections of the compound were given into the glutei muscles, on alternate sides, every day, dose from 3 to 6 c.c. There was absolutely no irritation nor any other untoward symptom in the injected areas. Over the affected knee the compound was applied full strength, on a gauze bandage, keeping this well moistened at all times; no irritation resulted. But on the fifth day the swelling seemed less hard. On the same day, March 17, 1912, the cervical glands showed decided decrease in swelling. The open sinuses of these glands had been injected with the compound, once every day, and this course was pursued until March 31, 1912, when all sinuses had closed. The cortical portions of these glands, however, remained greatly swollen, and there was never any change in this condition afterward. Microscopical examinations of the sputum were made every week. On April 25 (forty-three days after her first visit), *the sputum was found to be free from tubercle bacilli for the first time.* Subsequent weekly sputum examinations were negative. Cough is still present; expectoration in the morning only. May 21, 1912, she has gained 8 pounds in weight; weighs now 116 pounds. She sleeps well, has had no more night sweats since the second week of treatment by injections of the compound. On May 25, 1912, the right knee shows signs of returning motion, flexion and extension being possible to the extent of about 20 degrees. June 4, there being still further improvement in the motion of the knee joint, she scrubbed floors in the house of her sister, against strict orders. Has a slight hemoptysis consequent upon this undue exertion; the blood is free from tubercle bacilli. She weighs 120 pounds now. Her pulse and temperature had become normal since the third week of treatment. Slight infiltration and occasional râles continue at right apex, expectoration in the morning only. June 14, 1912, menstruation is now reestablished, there had been amenorrhea since November, 1911; she menstruates from now on regularly every twenty-eighth day. July 26, 1912, the right knee is now nearly normal in circumference; the outer bursa below the patella, however, is still swollen; motion is free and painless. From now now on injections of the compound were given only twice a week. This regimen was followed until Sept. 30, when the injections were discontinued altogether. By this time the knee was as useful as the sound left one, the bursa, before mentioned, still being swollen; no change in this condition took place hereafter. From October 1 she was given the specific inula by mouth, in 10 drop doses, four times a day, until the end of November. Her expectoration then amounted to less than one-half ounce in 24 hours, and was present only in the morning; there was no cough, the sputum being expelled by "clearing the throat." This sputum was examined under the microscope once every week, and was always free from tubercle bacilli. No infiltration being present at the right apex after December 15, her relatives took her back to Denmark about the middle of January. The only sign of disease remaining were the enlarged cervical glands; all other signs and symptoms had completely abated.

X-Ray Plates. We show four plates of two cases. In the one acute case of apparently recent origin, that of a young man, both lungs were extensively involved. After eleven months' treatment the lungs both cleared up, as shown in the plates. The second patient was a woman of forty years whose pulmonary tuberculosis was of four years' standing. She was discharged "arrested."

The *sputum reports,* mentioned under the heading of "inula," show in general that the sputum becomes negative after an average of from three to five months of treatment, unless the case be one of extreme involvement, in which instance the bacilli are completely destroyed only after a much longer time. Our sputum reports are parallel in nearly every instance with reports from local health departments, and are preserved with the full data of each case.

The general order of sequence in the *cessation of signs and symptoms* is first a reduction of temperature and pulse to normal or near-normal; next, the cough and expectoration diminish and the "Arneth count" shows return to normal. Phagocytosis is then found to be active and body weight increases. The last of all to clear up are the physical lung signs, tubercle bacilli being absent long before.

Arneth Count. As a rule, response to our method of treatment can be pretty accurately gauged by the repeated Arneth count. Whenever this count continues favorable the case will go on to recovery, unless complications intervene. Wherever there is no improvement in the Arneth count after two months of intensive treatment the case may be set down as a hopeless one. The "Arneth count" is a count of the polymorphonuclears (neutrophiles) and classifies these according to the number of nuclei they contain. Those with a single nucleus are placed in Class I, those with two in Class II, and so on. A normal count would give this approximate percentage among them: Class I, 5 per cent.; II, 35 per cent.; III, 41 per cent.; IV, 17 per cent.; V, 2 per cent. Cells of Classes I and II are younger cells and consequently not as vigorous in phagocytosis as are those of Class III, while those of Classes IV and V again are less active by reason of approaching cell division. A cell count showing the third class highest and also higher than Class I plus II, is regarded normal; a count showing the first two classes higher than the third is prognostically bad. Our studies, clinically and in the laboratory, show that even with a bad prognostic cell count the influence of the I-E compound will often reestablish a normal or nearly normal Arneth count, and raise the phagocytic index.

The table of blood examinations shows the effects of the compound upon the differential and Arneth counts. All of these were done by Dr. Schlauch.

It may be well to state here that we are not at all optimistic as to the outcome of *every* case treated under this method, especially those showing complications. We are not believers in a "consumption cure"; but we firmly believe in the discriminate medical treatment of tuberculosis. *Numerous other physicians who have used this method have reported most favorable results from it and their data are at the command of any inquirer.*

Conclusions. Our conclusions arrived at from a study of over 150 cases are as follows: The I-E compound (1) destroys tubercle bacilli; (2) increases phagocytosis; (3) favorably influences fever, reducing the temperature to normal; (4) materially asists in the elimination of toxins from the organism; (5) controls night sweats; (6) increases appetite and favors assimilation of food; (7) effects an arrest of the disease or a clinical cure in virtually all incipient cases and in about 50 per cent. of moderately advanced cases. In far advanced cases it has no appreciable effect.

Gas Intoxication Syndromes.—Voivenel and Martin make three syndromes, viz.: very severe, severe and medium, and mild. The first named presents hyperacute pulmonary edema, cyanosis, rapid pulse, etc.; the second offers a less marked edema with bronchitis. The third type makes itself felt in organs of least resistance so that there are several localized types, as pulmonary, gastroenteric, and nervous, characterized respectively by tormenting cough, abdominal pains, nausea, and constipation; and headache, backache and muscular weakness.—*La Presse Médicale.*

THE VALUE OF ROENTGENOLOGY IN HEAD INJURIES.*

By GERTRUDE W. WELTON, A.B., M.D.,

NEW YORK,

ROENTGENOLOGIST, NEW YORK POLYCLINIC HOSPITAL AND MEDICAL SCHOOL.

It is always a satisfaction to have work associated with the neurological surgical department, for in this branch of medical science diagnosis has become most exact. Certain signs and symptoms locate a cortical lesion in a definite area; others locate it at the base, in certain nerve tracts, medulla or pons, as the case may be. It is our ambition to determine the nature of the lesion as well as its exact location.

In the last few years since the development of transformers and vacuum tubes of such quality that ready penetration of the skull by the roentgen ray has been possible, roentgen diagnosis of intracranial lesions is becoming established. We are familiar with the normal markings of the skull, such as venous channels in the diploë, the grooves for the meningeal vessels, and the suture lines. With stereoscopic plates it is possible to look into the anterior, middle, and posterior fossæ and to recognize readily the bony structure of the base of the skull. It is in these three fossæ that the roentgenologist's great interest is centered to-day in the diagnosis of intracranial lesions, and I trust the day will soon come when that diagnosis can be as definite as is possible at the present time in gastrointestinal conditions.

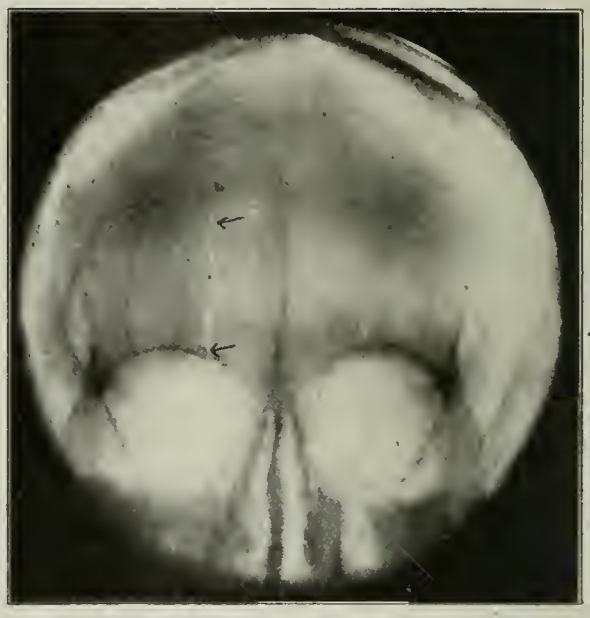

FIG. 1—Case 1. A. M., a child knocked down by an automobile, injuring his head. Longitudinal fracture of the vertical plate of the frontal bone. No pressure signs; therefore no operation.

Already much has been determined. We recognize the signs of increased intracranial pressure by the convolutional pressure atrophy of the vault, exaggeration of the markings of the vessels, and separation of the sutures in children. Characteristic changes occur in infectious processes involv-

*Read at a meeting of the Clinical Society of the New York Polyclinic Hospital on October 1, 1917.

ing the vault, tumors of the vault, chloroma for example, osteoma, osteosarcoma, and in the brain substance itself, tumors in which a deposit of lime salts has taken place.

Fig. 2—Case II. P. McC., a child, aged five years. Fell several stories injuring head. Fracture of the frontal bone extending backward and forking in the left parietal. Also separation of the saggital suture. Pressure signs developed requiring operation by Dr. Sharpe. Excellent recovery.

It is possible to differentiate tumors in the anterior fossæ giving pressure signs from the condition of internal hydrocephalus by the absence of sella changes in the former condition. Pituitary tumors show definite changes in the sella region due to direct pressure.

It is also possible to demonstrate acoustic tumors by the enlargement of the porous acusticus internus

Fig. 3—Case III. M. H., adult, showing a long oblique linear fracture through the squamous portion of the left temporal. No operation indicated.

on the affected side, as has been beautifully worked out by Dr. G. L. Carr of Boston. (See *Am. Jr. Roentgenology*, Aug., 1917.)

We are especially interested to-night in fractures of the skull. They are the most self-evident variations from the normal, the easiest to demonstrate, and their demonstration is of least value. The neurologist of to-day knows that as far as the immediate treatment of the patient is concerned, the presence or absence of linear fractures of the skull is of little moment. In head injuries, if intracranial pressure develops, and persists, this pressure has to be relieved, whether fracture is present or not.

We have had patients whose clinical pictures strongly indicated fracture, yet the roentgenograms did not confirm the diagnosis. We have also had patients with history of head injury who did not

Figs. 4 and 5—Case IV. A little child who fell several stories, injuring head. An extensive linear fracture passing in a horizontal plane from one coronal suture to the other. Operation indicated only on the third day. Excellent recovery.

have marked pressure signs, and it has always been more or less of a surprise to see the fracture lines in the roentgenograms. Fractures are much more frequent in head injuries than is commonly supposed.

The presence or absence of depressed fracture of the vault is quite another matter. It is in this type that the *x*-ray gives most helpful information as to the exact location of the defect, and the depth and extent of the depression of the inner table which necessitates an operative procedure.

Dr. Sharpe has had but one case of linear frac-

ture of the skull in which the roentgen findings were a guide to the treatment. This patient was examined the morning following an accident in which she was knocked down by an automobile. A short transverse linear fracture was located over the left

Fig. 6—Case VI. A little child who bumped her head some time ago. Recently the mother noticed a slight ridge over the right parietal region. Transverse fracture of the right parietal. This child had no special symptoms at the time of injury and has no signs of pressure at the present time, yet she has an extensive fracture of the skull; naturally no operation is indicated.

posterior parietal bone. Later, when pressure signs developed, in addition to the localizing signs demanding an operation, the decompression was done over the site of fracture instead of in the usual temporal region. An underlying extradural hemorrhage was found and removed; the patient made an uneventful recovery.

Most interesting are the cases of fracture which do not exhibit marked pressure signs, and these are the cases which do not come to operation; in this hospital, only about one patient out of every five cases of fracture of the skull is operated on.

The experience of this clinic confirms that of others that operative treatment in head injuries is determined not by the presence or absence of fractures, but by signs of increased intracranial pressure. Naturally, all depressed fractures of the vault should be elevated or removed for fear of later complications, particularly epilepsy.

A NEW METHOD OF TREATMENT OF INFANTILE PARALYSIS.

By ROY BERNARD, M.D.,

CHICAGO.

Acute anterior poliomyelitis, while not presenting an unfavorable prognosis so far as life is concerned, remains the bête noir of the profession because in spite of modern advances in bacteriology and serology no means are known to prevent the resulting motor paralysis, atrophy, and contractures of the extremities that usually follow the cessation of the acute phenomena.

I spoke of bacteriology advisedly because in the absence of a trumatic factor one cannot conceive inflammatory disease of the spinal cord to be produced by anything else than a microorganism. So long as the causative microorganism remains unknown that long will our therapy remain empirical and symptomatic without a specific influence on the cause of the disease.

With the subsidence of the acute phenomena, however, orthopedic and operative surgery are resorted to for the purpose of restoring in a roundabout way impaired function. Well and good, if the damage is limited in extent, for then the results are comparatively good considering the gravity of the situation; when, however, the damage involves a good deal of tissue the "curative" results leave much to be desired.

Years ago the thought struck me that in infantile paralysis some hope for success may be expected from any therapy likely to effect a regeneration of the affected structures, provided, of course, the entire cord has not been destroyed. With the central lesion restored to a more or less normal condition, the peripheral effects will disappear, if not spontaneously, certainly after a while, under the influence of measures to aid tone and nutrition of nerves and muscles, *e.g.* massage, exercise, baths, electricity, etc.

Bearing the pathology of poliomyelitis in mind it seemed plausible to me, at least theoretically, that in the absence of complete sclerosis of the cornua with

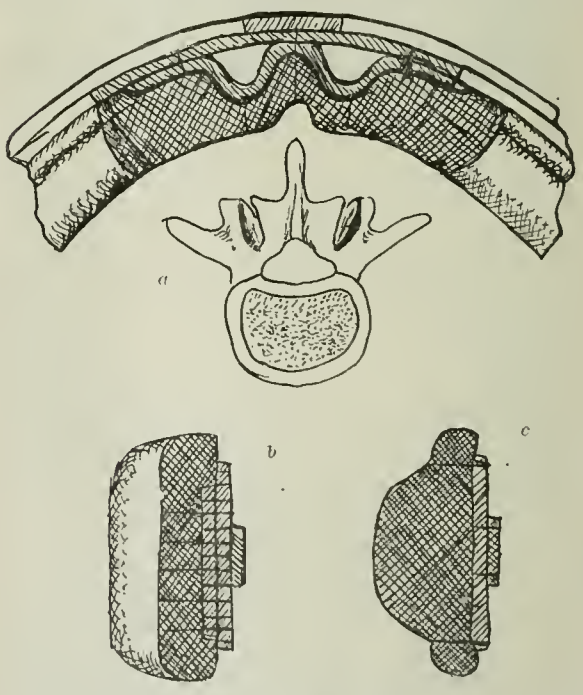

Fig. 1.—*a*, broken longitudinal sectional view of the appliance with sectional view of spinal column, showing body section of heavy leather, 4 in. wide, of a length sufficient approximately to encircle the body of the patient; a buckle-equipped strap permits of the appliance being fastened in position around the patient. Secured to the inner side of the body section is a strip of stiff leather bent in convoluted form—so formed as to present a recess midway between the ends of body section, opposite to which the padding is slightly depressed. The portion of the spinal column which is most susceptible to injury, *i.e.* the posterior process, is thus protected by the recess in the belt. The convolutions forming the recess cause the weight of the patient to be borne by those portions of the spinal column which extend at opposite sides of the posterior process, thus preventing undue pressure against the ribs. Four-inch padding of soft wool or other suitable material extends over the inner surface, held in place by cloth covering. *b*, cross section, center; *c*, cross-section, side.

total disappearance of the ganglion cells, regeneration of the structures may be possible by a physiological remedy, which was but recently restored to citizenship by Bier of Bonn (now of Berlin), namely, hyperemia.

The difficulty that presented itself seemed great, for one would have to produce a local hyperemia at two inaccessible places, viz., the cervical and lumbar enlargements.

The well known means of obtaining hyperemia in an accessible part of the body could not possibly be applied to the cord. Experiments with intense dry heat convinced me that even this powerful agent for hyperemization of tissues could not be depended upon to affect more than the superficial musculature and possibly the vertebral column. To reach the cord other methods would have to be brought into play.

Gradually I evolved a mechanical method, about to be described. Actual experiments with the consent of the persons concerned were undertaken creepingly and cautiously and only after repeated observations have I become convinced of the harmlessness of the procedure and its therapeutic efficacy. Later I ventured to demonstrate to a number of local and visiting colleagues that restoration of lost function by causing hyperemia of the cord after the subsidence of the acute phenomena cannot be doubted any more. In other words a therapy has been demonstrated that is not aimed at the peripheral results only but at the central causative factor itself.

Since then several physicians as well as myself have had ample opportunity to follow up a number of cases and no doubt being left as regards the permanency of the results, I feel free in describing my method with the hope that the profession will make equally good use of it in suitable cases.

Technique.—My first series of treatments were accomplished without anything save the physician's hands. The entire procedure consists of suspending the little patient between the hands of the physician and producing a number of rhythmic swingings calculated to put the spinal column on the stretch and to flood with blood the lumbar or cervical enlargement.

Simple as is this procedure, it was soon found to present certain difficulties, especially in larger children. In adults the weight of the patient would render the treatment physically impossible.

To obviate the possibility of error with reference to placing the leverage at the right place as well as to enable the physician to practice the swinging in a most convenient manner I have devised a simple suspension appliance, as shown in Fig. 2.

The patient when suspended therein for a minute or two is undergoing extension and relaxation of the spine without any effort on the part of the attendant. The appliance naturally leaves the physician's hands free to perform the swingings in a proper manner, the fulcrum being supplied by the appliance.

The treatment proper is carried out as follows: The patient is placed in the appliance of a size chosen for the special case. For the first two minutes the patient should be allowed to remain suspended undisturbed for the purpose of obtaining relaxation of the spinal column. This step is always to be taken at the beginning of all future séances.

The patient is now swung forward and backward with a jerk, somewhat in a manner used to bring down the mercury in a fever thermometer. If this maneuver is properly executed the lower extremities will invariably swing back in an opposite direction at the moment each movement has been completed. This simple procedure is executed fifteen to twenty-five times, depending on the tolerance of the patient.

The séance lasts about three minutes. Treatments may be given every other day or even oftener, all depending upon the reaction. It is noteworthy that when a reaction occurs it assumes in a mild form the phenomena of an acute anterior poliomyelitis.

In cases of paralysis of the upper extremities the physician will have to assist during the rhythmic swingings by supporting the extension with the palm of the right hand placed over the cervical enlargement and the left hand under the patient's chin, for it has been impossible to devise a suspension ring which will prove serviceable.

Fig. 2.—Suspension appliance.

In the event that both upper and lower extremities are involved treatments of the lower extremities should be given for some time and then followed by those directed against the upper paralysis.

A word of caution may not be amiss. Experience has shown that the suspension ring, which acts as a fulcrum, must be placed exactly over the largest part of either enlargement, as the case may be.

It will be recalled that the dorsal enlargement will

be found at the juncture of the XIth and XIIth dorsal, and the cervical enlargement at the juncture of the Vth and VIth cervical vertebrae. In all cases of the improper application of the fulcrum the results have not been satisfactory.

The astonishing results that have followed this simple treatment can be explained only by the fact that a hyperemia is produced in the affected portion of the cord. That whatever adhesions may be present will be broken up by the procedure described I have no doubt.

At this time it is scarcely necessary to enter into a detailed discussion of the therapeutic merits of artifically producing hyperemia. We owe it to the genius of August Bier that we have to-day a rational conception of its therapeutic indications and contraindications.

Hyperemia has above all a nutritive effect on cells. It is, of course, impossible to restore dead cells, but where atrophy and degeneration have not progressed far enough to destroy an organ completely, regeneration has been demonstrated so often as to need no further proof. While absolute proof is demonstrated only by histological methods, we have no other way to explain the clinical results.

After all, our greatest aim is to cure. The explanation of the cure may safely remain an academic problem. The gravity of infantile paralysis is serious enough to merit thorough investigation even on a purely empiric basis.

I append a few cases briefly described. As this is merely a preliminary paper.

Case I.—Agnes K., æt. 2 years 6 months, acute attack September 20, 1911. Previous history negative. Both arms and legs paralyzed. Treatment begun November 21, 1911. Slight motion appeared after the third treatment. Walked with some aid after the twelfth treatment. In this case the arms responded first. Discharged cured January 1, 1912.

Case II.—Julia M., æt. 18, attack January 6, 1913, both legs being involved. Treatment begun eight days later. In this case the muscles of the right leg and both gluteal groups had become very atrophic. The patient was discharged cured April 18. With complete functional restoration and disappearance of the muscular atrophy.

Case III.—T. B. B., female æt. 3, attack September 8, 1912. About a week later she was sent to Cook County Hospital where she remained until October 28. Motion was noticed November 11. In another three weeks the child walked about without any assistance.

Case IV.—Catherine E., æt. 11, had her attack in 1907 and was since treated by several physicians and irregular practitioners without any benefit. When I saw her on January 25, 1913, she had extensive atrophy of the leg, talipes and lateral curvature, and both arms and hands were involved. This case looked very promising on account of the length of time since the acute attack. It required only sixteen séances to bring about the most astonishing restoration of the disturbed functions. The atrophy and deformity of the foot disappeared and when she was discharged (April 12) she could jump the rope like any healthy child.

It would take up too much space to cite other cases, all of which seemed to respond uniformly. In recent cases very few séances were necessary to demonstrate even to the parents that functional improvement was present; in cases, however, in which the acute attack dated back some years, several weeks would elapse before decided improvement was noticeable. Once improvement was noticed the recovery proceeded very rapidly.

A few days ago (January, 1917) I got in touch with all the patients who have been away from my observation for several years. The reports I have received are so gratifying that I feel justified in saying that cures by this mechanophysiological method are also permament.

4721 Champlain Avenue.

A PLEA FOR MORE CESAREAN SECTIONS IN SELECTED CASES. THIRTY-FOUR CONSECUTIVE CASES WITHOUT MORTALITY TO MOTHER OR CHILD.*

By G. P. COOPERNAIL, M.D., F.A.C.S.,

BEDFORD, N. Y.

Only a few years ago cesarean section was looked upon as a rare and very difficult operation. In 1870 it was performed as the last and only hope of saving the mother. In 1880 the maternal mortality was 85 per cent. For the last ten years it is less than 10 per cent.

In clean, uncomplicated cases, A. B. Davis gives it as 2 per cent. In the summer of 1914 Prof. Karl Franz of Berlin gave us at one of his clinics a list of 150 consecutive cases with only three deaths. One case was complicated with pyosalpinx, the second was a bad case of endocarditis, the third was infected before she was operated upon.

By far the most common indication for this operation is contracted or deformed pelvis. The next in order is eclampsia and toxemia of pregnancy with convulsions at term with rigid cervix: then, placenta previa, with a central implantation with rigid cervix at term, neoplasms, and last of all for ruptured uterus during labor.

Are there not two border line cases where a cesarean section should be the operative procedure of choice?

First, the cases of moderately contracted pelvis, with a child with large head above the brim that does not engage, or after hours of labor may partly engage. The question is of relative relation between the fetal head and the pelvic diameters.

One of the most difficult and dangerous operations to both mother and child is the high forceps operation. Trying to extract a large head through a smaller bony outlet is far from being good surgery.

When there is no engagement of the head a high forceps operation is contraindicated. It is bound to result in more or less injury to the cervix, many lacerations of greater or less extent in the vaginal mucosa, and perineal tears. All are avenues of infection, not to speak of the injury to the child's brain from pressure, which may not become manifest until later years.

With a cesarean section in a clean case there should be no danger of the abdominal wound becoming infected and there is no danger of iniuring the child. Think of the hours of untold suffering the mother is subjected to before the birth of the child necessitates a high forceps operation. In these cases "let nature take its course" should be a thing of the past.

The second class which should come under the so-

*Read before the Westchester County (N. Y.) Medical Society, September, 1917.

called borderline cases are a certain number of breech presentations, with a pelvis that does not measure up to the normal standard.

Breech extractions are especially dangerous to the infant. The mortality is given as from 10 to 30 per cent. In private practice this is far too low. This is due not so much to the physician's lack of skill as to his being placed at a great disadvantage by surroundings and lack of trained assistants.

We are no longer justified in doing a craniotomy on a living child in order to deliver it through a contracted pelvis. The child's rights demand a cesarean section.

In a measure, does not the same question often come up in high forceps and breech cases? The breech presentations are abnormal ones, and necessitate operative interference. Leaving out the fetal mortality, consider the injury to the mother in rapid extraction of a breech presentation, such as multiple lacerations, and more or less hemorrhage, with perhaps hours of suffering, and later the danger of infection and prolapse. The cases with a large, roomy pelvis do not come under the borderline class.

The danger from cesarean section to the child should be nil. If we could determine the outcome of many of these borderline cases we would have many more sections than we do. No mother would refuse to submit to any operation in order to save her child's life, not to speak of her own suffering.

Placenta previa treated by tamponade and bags for dilation give a fetal mortality of about 80 per cent. By the Braxton-Hicks method you expect to lose the baby. Pankow gives a series of eight cases of placenta previa treated by cesarean section without a mortality to either mother or child.

The abdominal route is preferred by most surgeons, nearly all doing the low operation, that is making the incision below the umbilicus. A few men in this country make the incision above the umbilicus, but practically all the operators in Europe make the incision below.

Some of the advantages of the lower incision are as follows:

It is easier to control bleeding, especially if one should decide to amputate the uterus for a neoplasm. The abdomen can be protected more readily from the uterine contents. When membranes have been ruptured several hours and repeated examinations have been made, there is danger of infection.

In some cases there is a hernia of the uterus between the rectus muscles. The sheaths may be opened and the muscles sutured together. The Mayo's advise this method of closing the abdomen in midline incisions below the umbilicus in order to add strength to the abdominal wound.

In the series of cases ether was given by the drop without the preliminary hypo of morphine, as morphine tends to induce fetal asphyxia. A word of warning in regard to giving morphine previous to cesarean section. Out of the series of cases there was no trouble in resuscitating any of the babies, except in three cases where the mothers had been given a hypo of morphine, one-quarter grain, within two hours of the operation. In these three cases they were resuscitated only with the greatest difficulty. Atrophine sulphate gr. 1/150 was given one-half hour before operation to lessen bronchial secretions.

All incisions were made below the umbilicus in the median line. As soon as the incision was started a hypo of pituitrin was given. In making the incision keep in mind that during pregnancy all the abdominal layers are attenuated. Do not try to slash through with one stroke of the scalpel. There may be a loop of the intestine between the abdominal wall and the uterus. Make the incision large enough to deliver the child readily.

After the abdomen is opened two towels wet in saline are packed around the uterus, one on each side, which helps keep the fluid contents of the uterus from getting into the abdominal cavity. An assistant draws the upper end of the abdominal incision as far up as possible with a retractor. This is to enable one to start the incision in the uterus as high up on the fundus as possible. Incision can be readily made if the uterus is first delivered through the abdominal wound, but in order to do this it requires a much longer incision and takes more time. Always make the incision in the uterus in the median line, as there will be less hemorrhage. If we go through the uterus as high up as possible, after an opening is made large enough to admit two fingers, this can be readily extended downward between the two fingers just as one would extend an incision in the peritoneum. Avoid going too far in the lower uterine segment as one is apt to get severe hemorrhage there.

The incision in the uterus should be large enough not to tear the uterus in delivering the child; 12 to 14 cm. in most cases is sufficient. As soon as the uterine incision is made, grasp the child by one or both feet and delivery can be quickly made. It is not necessary to use forceps for delivery through the uterine incision.

After the first three cases, the uterus was not delivered before being incised.

Most of the children can be resuscitated by holding them by the feet, and applying friction to the spine, or by a few slaps on the buttocks. One-third of the infants had to be resuscitated by artificial respiration (the case where the mothers had been given morphine previous to the section). In most of the cases we did not clamp the cord until the child started to breathe. If, after applying friction to spine or slapping the buttocks they do not start to breathe, it is better to clamp the cord and start in with artificial respiration.

After the cord is cut, the uterus and placenta are lifted out of the abdomen, the soiled towels removed and clean ones placed under the uterus, the placenta is peeled out. If bleeding is excessive a towel is wrung out of boiling hot water and placed in the uterus for a few minutes. This is unnecessary, except in a very small percentage of cases.

If the cervix is not opened it is better to leave it and not try to dilate it with the fingers. The uterine contractions will dilate it in a few hours.

It was not necessary to ligate any of the vessels cut in the uterine incision. Bleeding can be quickly controlled by putting in five or six mattress sutures of No. 2 ten day chromic catgut. These sutures are of great importance in making a quick and easy closure of the uterus. Starting at the lower angle of the incision, be sure to put in the first suture at the extreme end or a little distance beyond the incision. The idea of this is to include all cut vessels. Place the suture about 2 cm. from the edge

of the wound going through to the mucosa. All text books caution about including the mucosa in your suture, but it will do no harm if one accidentally goes through it.

All the mattress sutures should be placed before tying. Tie them tight enough to control bleeding but not so tight so as to leach the tissues included in the suture. After they are tied, the edges of the wound will be slightly everted; these are brought together by placing sutures of No. 2 plain catgut in the center and between each of the mattress sutures.

If all raw edges are carefully tucked in, there will be no adhesions to the line of incision and in a few months the scar will be scarcely perceptible. There does not seem to be any rational reason why the uterine incision should be closed in layers like one closes an abdominal incision, for the structures in the uterine wall are the same all the way through, there being no layers of different tissue. It also takes more time in putting in three layers of sutures. If the abdomen has been well protected by towels, it is better not to mop it out and run the danger of destroying the integrity of the peritoneum.

Abdomen closed in layers, using interrupted chromic catgut for aponeurosis. Strap abdomen well with adhesive. The Boldt type of binder gives good support, and all cases are given a hypo of ¼ gr. morphia before leaving the table.

The question of ligating the tubes, or in the light of our present knowledge, the excision of a wedge-shaped section from each cornu of the uterus followed by careful closure of the opening to prevent future pregnancy, should be left to the discretion of the surgeon. A good rule to go by, providing the woman is otherwise in good condition, is to ligate the tubes after the second section. There is the question of losing the first child.

Out of the 34 cases all were for contracted pelvis except four. One a placenta previa, one a bad case of myomata, and the other two for eclampsia. All made good recoveries with primary union except one that developed ether pneumonia and got her dressings soiled. At the time of her operation she had a bronchitis and should have had local or spinal anesthesia.

The pneumonia, myomata, and eclampsia cases were the only anxious cases out of the series.

The woman with myomata was a negress. She had a large one impacted in Douglas' cul-de-sac; there were many others like knobs all over the body of the uterus. It was almost impossible to cut between them to get an incision large enough to deliver the child. The bleeding was very profuse, but in spite of the loss of blood she made an uninterrupted recovery. It would have been much better to have amputated the uterus, but both she and husband refused removal of the uterus.

The eclampsia cases were both at term without labor pains and with rigid cervix. Both cases had several convulsions before the operation. One case had as many as a dozen postoperative convulsions, and things looked pretty bad for the first 12 hours; from that time she made an uneventful recovery.

In three cases the placental site was under the line of incision, and it was necessary to go through the placenta and grasp the child's legs. No time should be lost in these cases.

One case had a second section. No special difficulties were encountered; there were no adhesions to the old uterine incision.

One of the patients operated upon would come under the so-called borderline cases. By giving you a short history, you may judge which is the better: To let nature take its course, and after hours of the most agonizing pain mortal is called upon to endure, to finish up with a high forceps operation or version, or do a clean cesarean section.

Mrs. C. B., age 37, born U. S. A. The conjugate diameter of brim measured about 3 inches. First child born 12 years ago. Was in labor 60 hours, then had to be delivered by high forceps. Eight-pound boy. Second child 2 years later; in labor 48 hours; head did not engage; child was delivered by podalic version; a 9-pound boy. Third child 1 year later; in labor 50 hours; head did not engage; delivered by podalic version; 9-pound boy. One of his arms was broken during the delivery. Fourth child born 2 years later; in labor about 48 hours: was delivered by high forceps; 8½-pound boy. Fifth child born a year later after 50 hours in labor; was delivered by high forceps; 8-pound boy. Had a severe infection following this labor. Was in bed 7 weeks and had phlebitis in left leg that gave her trouble for several months. She was too sick to nurse the baby or give it good care. Baby died when 4 months old. Two years later was delivered by a cesarean section of a 7-pound girl. At the time of her operation she was in poor condition, having been in poor health from the time of her last confinement. In spite of this she made an uninterrupted recovery. Mother and child both living and doing well.

The patient, a most grateful one, states that this is the only way she would give birth to children in the future. Her previous pregnancies were a constant nightmare to her, dreading the coming ordeal.

Cesarean section for one doing major surgery is far from being a difficult operation. Nevertheless, it is a serious operation for the patient, and should be advised only after careful consideration of all the facts presented in the case at hand.

It is well to keep in mind the saying that once a cesarean section, always a second cesarean. Mason shows that the theory that once a cesarean section always a cesarean section is a fallacy. That is, if the section is properly done for some cause other than a pelvic indication, the patient may safely go through labor as far as the cesarean scar is concerned. He cites a number of cases delivered normally after having been delivered previously by cesarean section—some two or three times. It is also well to consider the maternal mortality as given by conservative operators as being from one-half to 4 per cent. In regard to emboli, you may get them in a normal labor. On the other hand, it is a wonderful operation with sure indications.

War Eclampsia.—Franz seems satisfied that war diet cuts down eclampsia and that excessive protein and fat favor its appearance. He is not so sure about the enforced continence of war times as a preventive of the disease.—*Zentralblatt für Gynakologie.*

Peculiar Edema.—Maase and Zondek saw at Charité Hospital Medical Clinic, Berlin, from 30 to 40 cases of a peculiar type of edema in men between 45 and 60. The extremities, face, genitals, serous sacs, etc., were attacked. Patients also presented diarrhea, polyneuritis and cardiac disorders. Naturally, no one patient suffered from all of these accidents. All known types of edema could be excluded. The affection may have been due to defective alimentation for several patients at once recovered when fat was fed to them. Similar edema has been seen in nurslings fed on flour exclusively and in diabetics on the oatmeal cure.—*Deutsche medizinische Wochenschrift.*

Military Medicine.

THE SOLDIER'S HEART.

SOME months ago, the condition to which was given the term "soldier's heart" or the irritable heart of soldiers was discussed very freely in Great Britain by the first authorities on heart affections. Among those who ventured the opinion that the condition might be a manifestation of hyperthyroidism was Sir James Barr, who first in the *British Medical Journal* of April 15, 1916, and again in *American Medicine* for September, 1916, published papers on the soldier's heart and its relation to thyroidism. In these papers the writer attributed the so-called irritable hearts of soldiers to disorders of the thyroid secretion. However, the view was not generally held and it is therefore interesting to read in a paper contained in the *British Medical Journal* of September 29, 1917, contributed by Dr. Arthur F. Hurst that in his opinion hyperthyroidism and hyperadrenalism do produce disordered action of the heart. Hurst designates this condition the "harmonic type of soldier's heart." Any strong emotion, and particularly anger and fear, if not given the natural vent, in the case of anger by fight and of fear by flight, will give rise to abnormal suprarenal and thyroid activity. Hurst thinks that while the patient suffering in this way presents a picture of Graves' disease, the activity of the suprarenal glands is probably of greater importance, though less easily recognized than that of the thyroid. It will be observed that Hurst does not refer to hypothyroidism in this connection, nor did Barr mention the influence of the suprarenal glands, but the point is that they both ascribe to ductless glands the causation of many cases of irritable heart among soldiers.

The main symptoms are as follows: The pulse is rapid and the heart may be slightly enlarged. The blood-pressure of the average soldier in the front-line trenches is slightly subnormal, but in these cases it is always raised. The condition is accompanied by a very characteristic reaction which is present in no other; on moving the finger over the skin of the chest so lightly that in normal individuals no local reaction would occur, a pilomotor reflex is almost instantaneously produced. Goose skin is obvious and occasionally the hair can actually be seen to stand on end over the area touched by the finger and for some distance on each side. After about five seconds the pilomotor reflex fades away and is at once replaced by a vasodilator reflex; the blush, which may have a white border on each side, often lasts for several minutes. As improvement occurs the vasomotor reflex disappears, but the pilomotor reflex generally persists for a few weeks longer. Excessive sweating often occurs, sometimes in paroxysms, especially over the palms of the hands and soles of the feet, and the patient loses weight. The hands and occasionally the eyelids are tremulous, and the patient is highly nervous and excitable. The eyes are often slightly prominent and von Graefe's sign may be obtained. The thyroid gland, though overactive, is generally not obviously enlarged, but in some cases moderate enlargement is present.

As for treatment the patient must be isolated, at first, from the other patients in the ward by screens and should see only such visitors as the physician believes will allay rather than increase his nervous irritability. Mental activity and restlessness are lessened by small doses of opium (this, according to Hurst, being the only war neurosis in which the drug can be safely employed), and also by suggestion, especially when some special source of worry is present. The thyroid and adrenal secretions are kept in check by belladonna. Both Hurst and Barr are chary of employing *x*-ray treatment for such cases, as it is impossible to regulate the destructive action of the rays with sufficient accuracy for perfect safety.

ANTITOXIN FOR GAS BACILLUS INFECTION.

INFECTION due to *Bacillus welchii*, or the gas bacillus, as it is commonly called, is quite frequent in the present war and carries with it a high mortality. This fact has stimulated investigation anew, with the aim of developing, if possible, a prophylactic and therapeutic serum. Bull, experimenting on rabbits and guinea-pigs (*Journal of Experimental Medicine*, July and October, 1917), obtained a bacteria-free toxin from cultures of the organism, possessing the properties of an exotoxin. Animals injected with this toxin develop an immune serum which neutralizes *in vitro* the pathogenic effects of the toxin, and also has the power of preventing and controlling infections with the bacilli. These experiments put the gas bacillus in the same class with diphtheria and tetanus bacilli. When an antitoxin prepared in the horse was employed it was possible to confer on guinea-pigs a passive immunity of two weeks' duration, and, furthermore, guinea-pigs which had received a prophylactic injection of the antitoxin exhibited pronounced resistance to infection with the virulent bacilli for a period of twelve days. Established infections in guinea-pigs were arrested and controlled by treatment with the antitoxin. Bull believes that it will be possible to prevent gas bacillus infection in man through the prophylactic use of the antitoxin, and that developed cases of the infection may be controlled by therapeutic injections of the same agent. The antitoxin in man should be administered intravenously and probably locally about the wound.

Observations on the Etiology and Treatment of War Neuroses.—Life in the trenches is always accompanied by a state of nervous tension. Danger is ever present, and during periods of activity the night may only bring increased responsibility and anxiety instead of rest. Although most men become gradually accustomed to the sights and sounds, according to Arthur F. Hurst, unless regular periods of rest from the mental strain are given the majority of men gradually become irritable, restless, and unable to perform their duties satisfactorily.

He states that the sanitation of the army in France has been so efficient that the second great cause of neurasthenia—acute and chronic infections—has been less prominent than in any previous campaign. Aside from infections, prolonged mental and physical strain, toxemia, and severe pain lead to exhaustion by their direct action upon

the nervous system, and indirectly by their action upon the suprarenal glands, together with the liver and probably the thyroid. Prolonged muscular exertion and great emotions, especially fear and anger, have been shown to produce chromatolysis of the brain cells, together with definite changes in the suprarenal glands and liver.

The symptoms of neurasthenia in soldiers is about the same as that found in civil life. The symptoms described under the name of "soldier's heart" may be prominent. In most cases the blood pressure is low, corresponding with the fact that the blood pressure of the average tired soldier in front line trenches is slightly subnormal.

The treatment consists first of complete physical and mental rest. In most cases a small dose of bromide, such as gr. v, is given two or three times a day. Opium must be avoided, as it often aggravates the symptoms and increases the excitability and restlessness of the patient. No alcohol should be allowed; it is very badly tolerated by almost all patients suffering from war neuroses, and especially from true shell shock. A quantity which formerly produced no ill effect is often sufficient to intoxicate. Recovery is greatly accelerated by combating insomnia, as the exhaustion cannot disappear so long as the patient sleeps no more than three or four out of the twenty-four hours. Hurst has found that sodium diethyl-barbiturate (medinal) with acetyl salicylic acid (aspiran) gr. xv the best combination. The dose of the former should be between 10 and 15 grains the first two nights, after which it should be reduced by one grain every other night until only the latter (aspirin) is given, and the dose of this can then be gradually reduced. In intractable cases, especially if nightmares are present, suggestion under hypnosis is very effective. As soon as the patient is well enough to get up he should begin to help in the ward, and a few days later he should be given employment out of doors, for

The cure for this ill is not to sit still
And frowst with a book by the fire;
But to take a large hoe, and a shovel also,
And dig till you gently perspire.

The amount of exercise should be gradually increased, and the patient should not be discharged from hospital until he can do moderately heavy work, such as digging, without undue fatigue.

The emotion produced by a very horrible incident, such as seeing a friend killed whilst talking with him is sometimes sufficient to give rise to nervous symptoms. More commonly, however, such an event is only the culmination of a long series of emotional storms. In most cases, indeed, the final breakdown is not due to a definite incident, but is the result of the cumulative effect of fear, which gives rise to symptoms sooner or later or not at all, according to the temperament and the physical condition of the individual. It is often impossible to obtain an accurate history of the onset until the patient is convalescent, as in the early stages of his illness he is generally unwilling to talk about his experiences. Even after complete recovery, a horrible incident which was the exciting cause may remain obliterated from the memory, although it may have returned in dreams, or its nature may have been elicited from the patient during hypnosis.

The stress and strain of active service not infrequently result in a condition of mild confusion which may merge into deep stupor. The onset is often gradual and complete amnesia may result together with the stupor. Exactly the same condition may follow actual shell shock, but many of these cases are diagnosed as the result of shell shock when the mental stupor is really the result of emotion. It may also follow simple exhaustion, or it may represent an epileptic attack. In severe cases the patient lies inert, and involuntary micturition and defecation are frequently present during the first few hours. Complete insensibility is often followed by a dazed condition, in which automatic complex acts may be performed. The duration of stupor varies from a few minutes to several days, but it rarely lasts more than a week. It may suddenly pass away, the patient having no recollection of what occurred between the onset and the moment of recovery. More frequently, however, improvement is gradual.

Psychasthenia may be another result of prolonged mental strain, as represented by nightmares and day-dreams; obsessions and phobias are less common; tics are curiously rare. Nightmares are very common, and many men live through their most terrifying experiences night after night in their dreams. The dream may be forgotten, the patient only recollecting that he woke with a start and found himself in a cold sweat. Headaches usually follow, which disappear towards evening, and profound exhaustion occurs, with depression and loss of appetite.

The general treatment for psychasthenia is identical with the treatment for neurasthenia. In some cases the more prominent psychasthenic symptoms require special treatment. The nightmares may be stopped by the medinal-aspirin treatment, but when a dream has persisted for any length of time, nothing but hypnotism will remove it. This should, if possible, be practised at night so that the patient can pass from the hypnotic state into natural sleep, the suggestion being repeatedly made that he will not dream. A single treatment is often sufficient and it is rarely necessary to repeat it more than five or six times. Phobias and obsessions sometimes disappear after rest and "therapeutic conversations," in which the cause of the symptoms is explained to the patient, and he is encouraged to hope that they will quickly disappear as his general condition improves. It is of the utmost importance that his confidence should be gained and that he should feel that he can discuss his troubles with perfect freedom and without any fear of being misunderstood. In the severe cases suggestion under hypnosis should be employed without delay. The result, according to Hurst, is very satisfactory, and improvement often occurs with remarkable rapidity.

Tics are more resistant to treatment and reeducation is the most valuable treatment. Regular exercises are given for the affected muscles, and in order to gain that complete control over them the patient is made to inhibit the movements several times every day by an effort of will for a certain period, the duration of which should be slowly increased. Hurst cites the examples of soldiers with aerophagy and eructation tics, who were

cured by clenching a stick between the teeth whenever the desire to eructate was felt.—*British Medical Journal*, Sept. 29, 1917.

Postseric Tetanus.—Lumière has laid down ten dicta in respect to failure of serum to prevent the development of tetanus. 1. The action of serum in preventing tetanus is not absolute. 2. The duration of immunity cannot be estimated with precision because of a certain battle which goes on within the organism between the mischievous and defensive forces. 3. Postseric tetanus appears to be due to two principal causes, (a) superabundance of toxin formed in the wound over amounts of prophylactic serum which rearh the latter, and (b) liberation of latent tetanus spores either by a secondary surgical intervention or traumatism after the activity of the antitoxin has been exhausted (this refers to late postseric tetanus). 4. Early postseric tetanus, on the other hand, is chiefly due to imperfect sterilization of recent wounds and should be largely preventable; further, it may be well to repeat the injection in suitable cases. 5. Late postseric tetanus may be prevented in over one-half of the cases by an injection of serum before every secondary intervention. 6. In postseric tetanus serotherapy may be seen to modify notably the course of the disease. 7. In 15 cases out of 54 seroprophylaxis prevented the anchoring of the toxin to the nervous centers, so that only the motor nerves of the wounded limb suffered. 8. In 13 cases out of 54 the bulbomedullary centers were only partly protected. Late or incomplete trismus was then present with localized contractures. The prognosis in these cases is none too good. 9. When antitoxin has not protected the nervous centers trismus appears early and the prognosis is grave (26 in 54 cases). 10. Postseric tetanus must be treated by large injections of antitoxin given at the earliest possible moment plus symptomatic treatment. Contractures resist therapy but the paroxysms may be controlled by chloral, morphine, sulphate of magnesia, and persulphate of soda.—Lumière in *Annales de l'Institut Pasteur*, January, 1917.

Care of Soldiers' Feet and Regulations Affecting Organization in the Army.—The War Department has published regulations governing the orthopedic work of the Army. Medical officers in medical officers' training camps are required to have at least three periods of instruction of not less than an hour each in orthopedic work. Medical officers who elect orthopedic service will have intensive instruction in orthopedic surgery, and for men untrained in this branch the course will be of about six weeks' duration in a university. Line officers and candidates for admission will be instructed in the care of the foot and its coverings and the general principles of body posture. The simpler facts with regard to joint injuries will be given each candidate for a commission at officers' training camps. All enlisted men are given at least one hour's instruction in the care of the feet and its coverings and the treatment of minor injuries. A course of instruction will be given special enlisted men at the training camps and other stations to fit them for rendering proper assistance in shoe fitting and the treatment of minor orthopedic affections. Particular attention will be given by medical officers to the condition of the feet of enlisted men at the regular semi-monthly physical examination. An orthopedic surgeon will act as consultant in doubtful cases.

The Early Treatment of Gunshot Fractures of the Thigh.—C. Max Page and A. B. Le Mesurier, writing in the *British Journal of Surgery* for July, 1917, states that the primary operative procedure in gunshot wounds of the thigh, should be the establishment in all cases of satisfactory drainage once and for all and at the earliest possible moment after the injury. Repeated anesthetics and operations during the early period are to be deprecated in the treatment of these cases. The necessary procedure should therefore be effected at the casualty clearing station, where in any case the patient is anesthetized for cleaning up and the application of a splint. If practicable, the surface of the whole wound tract should be excised; excision on incision of the skin wounds alone is a useless procedure. All fragments of bone lying loose should be removed; if left, they are a frequent source of persistent local infection; and there appears to be no doubt that so long as the periosteum is not unduly damaged perfect union results, despite the loss of considerable amounts of compact bone. The writers prefer to pack the wounds so treated with dry sterile gauze. In the earlier cases of the series they employed tube drainage down to the bone from the posterior wound, but the limitation of infection seems to be better effected with the simple gauze pack. If the original wound or wounds do not furnish posterior drainage, a 4-inch incision should be made on the postero external aspect of the limb, and access gained to the seat of fracture along the line of cleavage between the outer hamstrings and the vastus externus, a part of the latter will have to be cut away in order to make the opening a free one. The gauze pack should be left undisturbed for two or three days, in the absence of signs of spreading infection; it should be removed and lightly renewed at intervals for a week or so, at the end of this period, in favorable cases, no further mechanism to keep the wound open will be necessary. A tube drain through the posterior hole down to the bone should be employed when there is evidence of continued osteitis and retention of discharge. In these latter cases a considerable saving in outside dressings may be frequently effected by passing the tube between two support slings and allowing the discharge to drip into a porringer. The outside dressings should be changed every twenty-four hours while acute infection is still active. During all processes the limb should be moved as little as possible, and it should never be necessary to roll the patient on his side for any purpose.

United States Medical Units Attached to French and British Forces.—There are 3180 medical officers, nurses, and members of ambulance sections of the United States Army now attached to the British and French forces. This total includes 870 medical officers and 470 nurses with the British forces and 40 ambulance sections, each of 46 officers and men (a total of 1840) with the French Army. This American personnel is only loaned subject to

recall and can, if the War Department so decides, be assigned to duty with the American forces. All wear the uniforms of the United States Army. Provision has been made for the training of 120 more ambulance sections at Allentown, Pa., all for eventual service with the French Army. A British Surgeon General, in commenting on the American medical officers, has said: "We are greatly impressed with the American medical officers; their keenness, energy, and quick perception are a positive tonic."

Health of Soldiers in Camps.—Col. Weston P. Chamberlain of the Surgeon General's Office, general sanitary inspector, has just returned from an inspcetion trip of American camps. He reports that the percentage of sick, practically all of whom are under treatment in cantonment hospitals, ranges from below one per cent. to slightly below two per cent. except at Camp Pike, where it is considerably higher as the result of measles among the men. It is pointed out that in this estimate are included all men in the hospitals and that in the Army a man is classed as sick and sent to the hospital for even the slightest indisposition, such as a cold, a mild tonsillitis, slight injury, etc. The only serious illness found at any of the camps was pneumonia. At Camp Sherman there were 43 cases in October in a command with an average strength of 19,000 men. Of these cases only three had died during the month, a mortality of seven per cent., against an average mortality for pneumonia in civil life of 15 to 20 per cent. The serum treatment for pneumonia is used at all the camps. The sanitary conditions in the camps far excels those generally pertaining in civil life and this is advantageously reflected in the health statistics of the Army. Each camp hospital has sufficient wards in operation to accommodate all the sick in the camp.

Order of Elks Gives War Hospital.—The Elks' War Relief Commission announces that the United States Government has accepted a gift of $250,000 from the Elks to provide for a large reconstruction hospital. This will be the first large reconstruction hospital in the United States where crippled and disfigured American soldiers will receive not only the best of expert medical attention but also instruction in various occupations which will aid in reestablishing them in civil life. The site of this hospital will be on Parker Hill, Boston, contiguous to the Robert Brigham Hospital.

Reception to Colonel Sir Berkeley Moynihan and Major Crile.—On the evening of November 9, 1500 physicians and their wives, belonging to the American medical services, met at the Waldorf Astoria under the auspices of the New York State Committee, Medical Section of the Council on National Defense, and listened to Sir Berkeley Moynihan, Senior Consulting Surgeon of the Royal Army Medical Corps of the British Army, discuss the war situation in general and the work of the medical service in particular. He stated that in the beginning of the war there were 30,000 doctors in England and that 10,000 of them had donned the khaki. Addresses were also made by Major George W. Crile, director of Base Hospital No. 4 in France, who has just returned from a six-months service at the front. Dr. Franklin Martin stated that the United States now had about 23,000 medical officers enrolled and about 14,000 commissioned. He predicted that about 35,000 medical men would be needed. Dr. George D. Stewart presided at the meeting.

Golf Tournament Swells Ambulance Fund.—The "Liberty Tournament," held by the United States Golf Association last July, has netted $72,275, which is to be used for the purchase of ambulances for the French front.

Allied War Losses Growing Smaller.—In response to a request that an official statement be made regarding casualties in the war to refute the lies spread abroad by the pro-Germans and pacifists in this country to discourage American patriots, Secretary Baker states that the ratio of losses sustained by all of the British expeditionary forces sent to France up to the present time has been less than seven men per 100. It is not expected that American losses will reach this percentage. The losses of the French are about in the same proportion. It is further stated that the losses are less to-day than in the earlier months of the war because of improved tactics and the swiftly amounting allied superiority in artillery.

Red Cross Appropriations for Relief Work.—In accordance with its new policy, the American Red Cross has made public a statement regarding its finances. The Red Cross had received up to November 1, $79,895,355.68 to be applied to its war funds. Of this amount $19,581,240.47 has been apportioned to relief work in France. The total appropriations from the war fund up to November 1, amounted to $40,851,259, of which $26,934,416 was for foreign relief. The foreign relief appropriations were apportioned as follows: France, $19,581,240.47; Belgium, $720,000; Russia, $4,428,040; Serbia, $493,203; Roumania, $1,518,398; Italy, $214,000; Great Britain, $1,066,520; foreign miscellaneous, $113,012; Armenian and Syrian Relief, $1,800,000. There was appropriated to United States supplies, etc., to United States forces, $2,448,729; for United States hospital work, $379,500; for United States sanitary service, about cantonments, $183,500; for United States miscellaneous items, $108,487. Other appropriations advanced for hospital funds amounted to $220,000. Of the collection made, $9,129,389 has been reserved for return to Red Cross Chapters to be spent for war relief work. In addition to the above, the Red Cross has handled $1,417,625 which has been appropriated for specifically stated purposes.

German Criminals Again Attack Hospital.—German aviators dropped bombs on the French Hospital at Zuydcoote on November 9. Eleven persons belonging to the hospital staff were killed and nine were wounded.

Alcedo's Surgeon Saved.—Dr. Paul Andreae who was a surgeon on the U. S. patrol steamship *Alcedo*, which was sunk by a U-boat a couple of weeks ago, has cabled to his father in Jersey City that he was among those who escaped drowning. Dr. Andreae entered the naval medical reserve corps immediately after the declaration of war.

MEDICAL RECORD.

TRAUMATIC INTRAPERICARDIAL HEMORRHAGE.

PENETRATING wounds of the heart and pericardium that reach the operating table are rather rare; hence the report of two cases operated upon by Rhodes (*Annals of Surgery*, July, 1917) seem worthy of mention. Rhodes says very truly that few traumatic lesions of the thorax demand operative relief, but in cases in which there is profuse hemorrhage into the pericardial sac, interference must be prompt, and no considerations such as the critical condition of the patient must be allowed to prevent operation.

The first patient whose case he records had been stabbed with the large blade of a pocket knife, which had cut through the left fourth costal cartilage and had been driven into the chest the full length of the blade. There had been free bleeding at first but later the flow decreased. When the patient reached the hospital there was severe dyspnea with gradually increasing cyanosis of the lips. The heart sounds were barely audible. A rectangular osteoplastic flap gave an excellent exposure and was made in the following manner: A vertical incision was made over the middle of the sternum, extending from the second to the fifth costal cartilage. From each end of this incision, five inch horizontal incisions were made, the soft tissues were reflected outward and the cartilages of the third and fifth ribs were divided subperichondrially, the fourth already having been divided at the time of injury. The upper and lower intercostal spaces of this area were then incised and the whole osteoplastic flap bent backwards, breaking the ribs at the outer portion of the wound. It was found that the stab wound involved pleura and pericardium and that the pericardial sac was filled with blood from a wounded pericardial vessel, but the heart itself had not been injured. The patient's condition improved remarkably as soon as the imprisoned blood escaped from the pericardial sac and the pressure on the heart was relieved. Rhodes then realized that he had been dealing with a case of heart tamponnade and that the respiratory and circulatory symptoms were due to that and not to pneumothorax. The bleeding vessel was tied and, after free irrigation of the cavity with salt solution, the pericardium was closed without drainage. The patient left the hospital with normal heart and lung action on the nineteenth day.

The second patient had also been stabbed in the chest shortly before admission and was almost moribund. He had lost a large amount of blood, the pulse was very bad, heart sounds were inaudible over the pericardium, there was very pronounced pneumothorax, with moderate dyspnea and slight cyanosis. Immediate operation was performed by the same technique as in the previous case. Free incision of the pericardium was followed by a gush of blood and the patient's condition improved temporarily. No bleeding point was found on the pericardium or anterior surface of the heart; but blood continued to well up, keeping the sac fairly full in spite of vigorous sponging. Upon lifting the heart forward a rent was found in its posterior surface. An attempt was made to suture the wound but this was found to be impossible, as the heart ceased to beat whenever it was rotated or lifted up sufficiently to expose the field. Death occurred within half an hour. The remarkable feature of this case was that the wound appeared to be on the posterior surface of the heart. Autopsy showed that this was due to the fact that the extensive pneumothorax had resulted in a partial rotation of the heart on its longitudinal axis, and that the surface which had been anterior at the time of the receipt of the injury had become posterior by the time of operation; yet attempts to rotate the heart back to its normal position in order to place the sutures had resulted in the cessation of its pulsations.

From the study of these two cases Rhodes reaches the conclusion that in all cases of stab wound of this nature extreme symptoms of respiratory embarrassment should be considered as caused by heart tamponnade and not by the pneumothorax alone, and that this tamponnade must be relieved immediately.

THE HISTORY OF SMALLPOX.

FROM the first mention of this disease in the history of medicine, it has always been described as one of the great scourges of mankind. Moore in his "History of the Smallpox" refers to the singularity of the happening "that the smallpox, the measles and Mahomet should all spring up in the same year in Arabia for the disturbance of the world." The year was A. D. 570, also the date of the war of the elephant. According to Mohammedan legendary history, in this year Abrahah, the Abyssinian viceroy of Yemen, as a reprisal for the profanation of the Christian church he had built in the capital, Saana, by emissaries from Mecca, whose holy place, the Kaaba, was being beglected, advanced with a large army against Mecca; he was mounted on a huge elephant, which, according to the story, refused to go forward, while at the

same time a flock of enormous birds came over from the sea, each with three small stones, one in the bill and two in the talons, which they dropped on the Abyssinian army, and wherever the stones struck wounds and pustules broke out, and the entire host was destroyed.

As to the case of smallpox, while Creighton and his followers contend that it is a skin disease of the nature of lichen turned pustular, this theory of causation is not in accordance with the views of the majority of pathologists who have made a special study of the disease. These will agree rather with the opinions given by Dr. A. E. Cope in the *Medical Officer* of September 29, 1917, and which are as follows: In the first place the whole of the facts are in favor of the smallpox group of diseases being primarily and ultimately infective; not primarily constitutional diseases of non-infective type, and only secondarily communicable by contagious inoculation or infection, but right throughout as truly infectious diseases as all the other exanthemata. The sole difficulty, as Creighton well realizes, is the pustular nature of existing smallpox, and when he speaks of lichen turned pustular and later becoming contagious, Cope's suggestion is that the epidemic element was primary and essential, but that in the course of development it had grafted upon it a pustular element which, while at first casual and secondary, became ultimately almost inseparable from it. The clinical history of smallpox affords further evidence in the same direction. Therefore, although there is a good deal to be said for smallpox having been originally an infectious exanthem very like measles, but with a secondary pustular element which may or may not have been constantly associated with it from the commencement of its history, there seems to be little to support Creighton's view, that a simple lichenous non-infectious skin rash took on pustular and at the same time infectious properties in the year A. D. 570 or thereabouts and has maintained the same type ever since. The mass of evidence points to the belief that smallpox must have been *ab initio* a general rather than a local disease.

Moore brings forth a considerable amount of testimony to show that smallpox had been known in India and China from very remote times. He explains the failure of the disease to spread from these countries by the fact that the separation of India, and much more of China, from Europe was rendered very complete at that time by the existing necessity for journeys across deserts or over sea and, in consequence, the time taken in the journey would itself wear out any smallpox infection before the transit was made. It was only when the Persians overcame their repugnance to maritime commerce that they acted as intermediaries between West and East, and with their coasting trade in silks, muslins, spices, pearls, and other precious commodities would easily bring smallpox to the Arabian and Egyptian shores.

Ahron or Aaron, an Arabian physician, was the first to write concerning smallpox. His works are lost, and all we know of them is from references to them by the famous physician and clinician of Baghdad, Rhazes, who lived at the end of the ninth and early part of the tenth centuries, and who quotes from Ahron's treatise on smallpox. Rhazes' description of smallpox, therefore, is the first written description extant of the disease, and notwithstanding that he somewhat confuses smallpox and measles, is the earliest clear account of smallpox, and reproduces all its well known characteristics. It must be borne in mind, however, that between Ahron and Rhazes a period of 300 years had elapsed, during which time the disease had made extraordinary strides.

NASOPHARYNGEAL SURGERY.

PERHAPS no other form of special surgery results in such immediate and permanent improvement as the surgery of the nasopharynx. In children especially operations on this tract for the removal of the common respiratory obstructions cause so much improvement in the general health and development of the body, but especially of the mind, as to be almost miraculous. In the young the removal of these obstructions to free breathing changes the entire bony contour of the face and jaw bones, as well as increasing the depth of the chest. In the case of the chest this increase in depth is brought about by the freedom of motion given to the chest walls and auxiliary muscles of respiration. While the results in the adult are not nearly so striking as in the young, the general benefits from appropriate and well-advised nasopharyngeal surgery are so marked that treatment by the rhinologist is deemed as necessary, and is therefore almost as universal, as treatment by the dentist. But as is to be expected in so new and prolific a field the work is often taken up after inadequate training and by incompetent persons. Bad results, therefore, are not justly placed at the door of the limitations in this particular field but rather to poor technique or inadvised selection of cases. It must be remembered that nasopharyngeal operations are undertaken in a field that lies very close to and only poorly separated from the brain and from the large blood-vessels going thereto. One is always in danger of infecting or wounding these structures unless great care is taken with asepsis or a thorough understanding is had of anatomical relations. This entire field is either in an almost inaccessible place or is exceedingly restricted in area. In order to do good work the operator must have a special temperament and attain special skill for work in these miniature fields.

In nearly every other branch of major surgery the field of operation is free and accessible, aseptic precautions are easily taken, and the control of hemorrhage is not a chance matter. In the nasopharynx on the other hand, while these require-

ments are as great if not greater, aseptic precautions are impossible to carry out, hemorrhage is difficult to control, and the field of operation is at a distance from the operator, to be reached only by instruments. The disinfection of the field is out of the question, and the only aseptic precautions are those possible with the instruments and with the person of the operator. The question of anesthesia is always a disturbing one. Local anesthesia for adults is the usual choice, although, because of the greater delicacy of the operation, more control of the patient would be desired than is obtainable under local anesthesia. In other major surgical operations the place for such operations is usually in a hospital with all the advantages that a hospital offers. Nasopharyngeal operations are usually carried out in a freelance fashion without any of the usual surgical necessities of major operations. Naturally, there is no control of the patients and no opportunity to study or to keep track of after effects or even of the mortality of these operations. Until recently the mortality factor of these operations received no consideration. Fatal hemorrhage sometimes occurs, meningeal infection is not excessively rare, and permanent injury to some portion of the bony portions of the face, such as septal perforation, destruction of the bridge of the nose, antrum infection, etc., is not unknown. Moreover, while general surgery is never undertaken without a thorough study of the patient's constitution in order that the surgical risk may not be increased by operating on unsuitable cases, in nasopharyngeal operations such precautions are often omitted because the operations are not considered major ones. Yet while general surgery has a dash that this apparently petty surgery has not, the latter has all the dangers of the former while at the same time calling for greater delicacy of technique. The decision for surgical interference must be as mature here as elsewhere, if fatalities are to be avoided. It is this judgment that distinguishes the surgeon from the operator.

PHYSIOLOGY OF ENDOGENOUS URIC ACID.

ENDOGENOUS uric acid is formed by some sort of synthesis in the body, as is shown when the subject is placed on a purin-free diet. As with most questions which seem simple, the nature of the synthesis has been the theme of much controversy, which has been due in part to contrary finds.

Host has recently published an interesting contribution to this study ("Bidrag til den Endogene Urinsyres Fysiologi," Kristiania, 1917) which which seems to open up a new line of investigation. Researches were carried out on 17 persons, two of whom were quite normal, while the others were either convalescents or patients who were free from any taint of arthritis urica. This material was controlled for a long period for study of the fluctuations in the uric acid content of the blood and urine. In no subject was the elimination constant from day to day. Upon a fixed diet this figure did exhibit constancy in a few subjects, but in the majority there was marked fluctuation—either extreme irregularity or a variation of up to 80 per cent. from day to day. Even in subjects with a certain regularity the latter was dependent on various factors of which the chief was the composition of the food. An increase or decrease in the latter was shown in the urine; that is, with an increase of food calories of 20 to 30 per cent., uric acid was increased in the same proportion. The source of the calories, whether protein, carbohydrates, or fat, did not affect the general result, although when albumin was given more of the acid was eliminated. The largest amount of acid was excreted in the morning or first part of the forenoon and the least during the afternoon and night. In the two first periods of the day the amount of acid rose after meals. Diuresis and the hydrogen-ion concentration were without influence on elimination of endogenous acid. Increase of temperature and certain drugs, notably asperin, caused notable increase in excretion. The amount of endogenous acid in the blood varied from a minimum of 0.5 to a maximum of 2.68 mg. per 100 c.c. of that fluid. In 70 per cent. of the material the amount was between 0.01 and 0.02 per 1,000.

The blood content was constant for certain individuals, but in others there were marked fluctuations, as there are between different subjects as a result of individual peculiarities. The conflicting results and views on this problem must be due largely to the two types of individual who show respectively constant, or nearly constant, formation and excretion of acid, and great fluctuations in the same.

TETANOPHOBIA.

THE phenomenon of tetanophobia, *i.e.* a general fear of lockjaw, is not new, for it is supposed to prevail in any large community after a series of tetanus deaths. It is not surprising, therefore, to find an account of tetanophobia in the fighting forces in Europe and according to Couteaud, writing of the vicinity of Cherbourg, this fear has extended to the civilian population. It apparently is by no means in direct proportion to the number of victims, especially those with insignificant wounds. To-day everyone with an abrasion demands an injection of antitoxin and it is becoming increasingly difficult to dispose of these demands. The agriculturists are relatively spared, contrary to what one might expect; they are always injuring themselves, yet pay no attention to their slight knocks. To explain this fact the author assumes the possibility of minimal infections leading to artificial immunisation. In the Cherbourg section about 60,000 wounded have been treated since the beginning of the war, and of this number 58 only developed tetanus, with 37 deaths. It is difficult with such a record to understand the general fear of the disease. This is due perhaps to the cases occurring early in the war, yet most of these cases developed in the severely wounded. It is difficult to understand how one case per 1,000 wounded could cause a panicky state of feeling in

a community. The history of Fourth of July tetanus in the United States shows that the public itself can be quite indifferent to the dangers of a disease which formerly claimed many hundreds of victims annually.

BABY KILLING.

A CHICAGO euthanasiac has broken into the newspapers with an improved scheme of taking life. He first entered the limelight a year or two ago upon announcing to the world that he would not perform an operation on a monster in order to prolong its life for a few days. As this abstention from a useless operation was not a heinous crime, and would be approved by many medical men, the notoriety achieved was only moderate. The next venture was a plea for shortening the nursing curriculum; this fell flat, and didn't get even a three-line notice on the inside page. But now he is getting real headlines and an occasional editorial reference for an open attempt on the life of an unoffending baby who had the bad karma, as the Hindus say, of being born hydrocephalic. The new arbiter of human destiny megaphones to an otherwise occupied world that he is giving the infant a mysterious drug which will gradually sap its vitality and finally shove it across the Styx. Why, if he is really working the philanthropy racket, he doesn't kill it at once with a good dose of morphine, or a cord round the neck, is not revealed; it wouldn't take so long, and the newspaper sob stuff would be shorter—but of course that's not the reason. When the baby dies, and the coroner makes inquiries, we shall perhaps get fuller particulars of this latest frill in infanticide.

News of the Week.

Life Insurance Company Offers Statistics to Physicians.—The Statistical Bureau of the Metropolitan Life Insurance Company announces that in view of the cooperation which the medical profession has given them in the collection of data, they desire, now that their statistics have been compiled, to place them at the disposal of the medical profession. These statistics present the principal causes of death among white and colored wage earners in the United States and Canada. The material covers over ten million individuals for each of the six years from 1911 to 1916. Death rates are available for each race, by sex and by age periods. The company hopes in this way to aid in the study of disease and disability among wage-earners. It desires to stimulate medical investigation and research. These statistics are available to physicians, public health, and social workers. All inquiries should be addressed to the Statistical Bureau, Metropolitan Life Insurance Company, 1 Madison Avenue, New York City.

Are Physicians Reporting Tuberculosis?—The statistics of the New York Health Department with reference to tuberculosis in the second quarter of the present year show a slight decrease in the death rate from pulmonary tuberculosis and for other forms of disease as well, while there is a marked decline in the number of new cases reported. The Health Department states that this would be a source of great satisfaction did it not have evidence for the belief that this decrease can be accounted for to a certain extent by the failure of physicians to report to the Health Department cases of tuberculosis under their care. Delinquent physicians are reminded that failure to report cases of tuberculosis is a violation of the Sanitary Code, that is, a misdemeanor and subjects the offender to criminal prosecution.

"War Whiskey" Fatal.—The death of five men and the serious illness of two others who had been living in a Mills Hotel in Bleecker Street, were reported on one day last week. Investigation revealed the fact that they had obtained a substitute for whiskey at a Bleecker Street saloon. The symptoms of the victims pointed to wood alcohol poisoning. An autopsy has been performed on the body of one of the victims and further investigations are in progress.

High Price of Milk and the Poor of New York.—In order to determine how the high price of milk is affecting the people of New York, the Department of Health, in cooperation with the New York Association for Improving the Condition of the Poor, and the Mayor's Committee on Milk, has made a survey representing all the boroughs. The information was collected from 2200 families by 250 field workers. The 2,200 families visited represented 12,439 individuals. of which 4,467 were adults, 2,534 children from six to sixteen years of age, and 5,438 children under six years. The total amount of milk purchased by these families at this time was 3,193 quarts daily, as compared with 4,797 quarts daily a year ago. Though this decrease is slightly offset by the consumption of condensed milk, the amount falls short of the estimated requirement for this number of people, which, according to the estimates of physiologists and pediatricians, would be 8,194 quarts daily.

White Mice Wanted.—The laboratory of the New York Health Department is suffering from a shortage of white mice as the result of war conditions and the increased cost of breeding animals. Dr. William H. Park, director of the laboratories, is advertising for all who have white mice for sale to communicate with the Research Laboratory, foot of West Sixteenth Street, New York. Unless a new supply of white mice is furnished the Health Department will be forced to discontinue testing pneumonia germs for the physicians of the city.

Progress in the Prevention of Blindness.—Recently published statistics concerning the occurrence of ophthalmia neonatorum in the schools for the blind throughout the United States show that altogether 3336 pupils were enrolled in these schools during 1916-1917, and that nearly one-quarter of them were blind as the result of ophthalmia neonatorum. The records of the past ten years show that in 1907-1908 26 per cent. of those admitted to these schools were blind as the result of ophthalmia neonatorum and that each succeeding year has shown a slight decrease in the number of cases of blindness due to this cause until in 1916-1917 but 18.4 per cent. of those admitted were blind as a result of ophthalmia neonatorum. Of these 3336 children admitted to schools for

the blind in 1916-1917, 341 were blind from accident, 121 from progressive nearsightedness, 56 from trachoma, 189 from interstitial keratitis, 334 from optic nerve atrophy, 947 from other congenital defects and one from wood alcohol poisoning.

Commission Conducts Hearing on Care of Insane.—The Hospital Development Commission, which was created by the last Legislature of the State of New York to formulate a plan for the systematic enlargement of the State institutions for the insane and feeble-minded, conducted a hearing at the New York Academy of Medicine, on November 7 and 8. The Commission has been engaged since last July in visiting and investigating the state hospitals for the insane in this and other states, particularly Massachusetts, in the endeavor to devise a method of handling the insane in State and municipal institutions, and to evolve a plan which will provide for the expansion of the state hospital system without requests for appropriations at each session of the Legislature. The immediate establishment of psychopathic hospitals was advocated. These could care for many patients who did not need State Hospital care and would serve as a clearing house for sifting out the cases that were hopeless and belonged in hospitals for the insane from those who needed only temporary care. The hearing brought out the opinion that the care of the insane should be exclusively a state function, as municipal governments were too liable to shift.

The Yorkville Medical Society of the City of New York will hold a stated meeting at the Hotel Bon Ray, Madison Avenue and Ninety-second Street, on Monday evening, November 19, at 9 o'clock. There will be a symposium on tuberculosis, with papers by Drs. I. Seth Hirsch, A. F. Shrier, Jacob Heckmann, and Fritz Neumann.

The Medical Association of the Greater City of New York will hold a stated meeting at the New York Academy of Medicine on Monday, November 19, at 8.30 P. M. There will be a series of "Practical Talks on the Diagnosis and Treatment of Infectious Diseases" by Drs. Harry Louis Abramson, Josephine Bicknell Neal, and Samuel Dana Hubbard, followed by a discussion by Drs. William Lang Sommerset, John Randolph Graham, Louis I. Harris, Charles H. Nammack, and Aaron Silkman.

Dr. William M. Leszynsky has been appointed neurologist to the Manhattan State Hospital, New York City.

Prof. F. de Quervain has been appointed to the surgical chair held by the late Professor Kocher at the University of Berne, Switzerland.

The Joint Meeting of the New England Pediatric Society, the Philadelphia Pediatric Society and the Section on Pediatrics of the New York Academy of Medicine, was held in New York on November 8. A purely scientific session, such as has been held in former years, was dispensed with. The day was spent in visiting clinics, among which were the following: Children's Wards of Bellevue Hospital, a Clinic by Dr. Linnaeus E. LaFetra, Dr. Herbert E. Wilcox, Dr. Charles Hendee Smith, and Dr. Oscar M. Schloss; Neurological Institute, A Clinic on "Newer Methods of Diagnosis and Treatment of Hydrocephalus," by Dr. Charles A. Elsberg, and a Clinic on the "Surgical Treatment of Birth Palsy," by Alfred S. Taylor; Babies' Hospital, a Clinic by Dr. L. Emmet Holt; Vanderbilt Clinic, a "Dermatological Clinic," by Dr. George M. MacKee; Department of Pathology, College of Physicians and Surgeons, "A Demonstration of Pathological Material," by Adrian V. S. Lambert, and a "Neurological Clinic," by Dr. Frederick Tilney. A dinner was given at the Harvard Club which was followed by after dinner addresses on the "Pediatricians' Part in the War." Dr. Herman M. Biggs described the conditions among the civil population of France—the low birth rate, the increase in tuberculosis, and the losses incident to the war—that make it imperative that every effort should be made to conserve infant life. For the work to be done along these lines they were largely dependent upon American physicians. Dr. Samuel McC. Hammill and Dr. Richard M. Pearce described the work that was being done to conserve infant and child life in Pennsylvania and Dr. Fritz B. Talbot told of the work that was being done along similar lines in Massachusetts.

New York Food Cabinet Organizes.—Dr. Henry Moschowitz, the City Market Commissioner, has organized a group of representatives of the various city departments which is to meet once each week to discuss ways and means of establishing the control of food in New York City. The first of these meetings was held on November 7, when a plan of campaign was outlined. The task of the Health Department of the City is to make a study of the wholesale and retail prices of the essential commodities and the relation of these prices to the factors of distribution of trade. The Department of Public Charities is to study the relation of present prices to income.

The Jamaica Hospital, Borough of Queens, New York City, announces the instalment of a thoroughly equipped *x*-ray laboratory and states that it is prepared to make *x*-ray examinations and report upon them to physicians referring cases to it.

Publication to Aid Orphans of the War.—The Association of Orphans of the War announces that it has founded a magazine bearing the title, "The Orphans of the War," which is to be a universal magazine of French propaganda. The object of the publication is to form a link between the orphans of the war and their friends who will thus be able to support them in their daily life and to aid in rearing a healthy and strong generation of men and women who will work for the greatness of France and the progress of Humanity.

Distinctive Bottles for Poison.—A recent bulletin issued from the Surgeon General's office at Washington states that every year, on an average, five thousand people take poison accidentally. To prevent these mistakes a bottle has been invented which has the skull and cross-bones molded deep in the glass, so that when the bottle is taken up in the dark it can be easily distinguished by the sense of touch. If the label from such a bottle is lost the fact that it contains poison will still be obvious.

Charitable Bequests.—Among sixty-eight beneficiaries of the will of the late Mrs. Mary Warden Harkness are the following hospitals: Morristown

Memorial Hospital, $100,000; Flagler Hospital, $100,000; Germantown Dispensary and Hospital, $100,000; Babies' Hospital and St. Mary's Free Hospital for Children, New York, each $100,000; St. Bartholomew's Clinic, New York, $10,000; St. John's Guild, New York, $50,000.

St. John's Guild and the Hebrew Orphan Asylum, New York, have each received $500 under the will of Joseph Morningstar.

Dr. Katherine B. Davis has been reappointed chairman of the Parole Board of New York City for a term of ten years by Mayor Mitchel, at a salary of $7,500 a year.

Obituary Notes.—Dr. CHARLES H. A. DAVIS of Meriden, Conn., died at the State Hospital, Middletown, Conn., on November 8, aged 77 years. He was a graduate of New York University Medical College, in 1865, a former member of the Legislature, and twice Mayor of Meriden.

Dr. BASIL M. WOOLLEY, a graduate of the Atlanta Medical College, in 1882, and a Confederate veteran, died at his home in Atlanta, Ga., on October 28, aged 83 years.

Dr. JOSIAH JACKSON HARRISON, a graduate of the University of Nashville Medical Department, in 1854, and a practitioner of medicine for over sixty years, died at his home in Loudon, Tenn., on October 24, aged 83 years.

Dr. JEFFERSON A. DAVIS, a graduate of the Medico-Chirurgical College of Kansas City, in 1902, died at his home in Kansas City, Kas., on October 28, aged 54 years.

Dr. CARL FULDA of Brooklyn died at Pepperell, Mass., on October 8, aged 39 years. He was a graduate of the College of Physicians and Surgeons, Columbia University, in 1900, and a member of the second surgical staff of the German Hospital, Brooklyn.

Dr. HANS KUDLICH died at his home in Hoboken, on November 10, at the age of 94 years. He studied medicine in Berlin and Switzerland and was banished from his country for having taken part in an abortive revolution in Germany. He was one of the founders of the Hoboken Academy of Medicine.

Dr. LOUIS ARTHUR WELLES ALLEMAN died at his home in Geneva, N. Y., on November 3, aged 51 years. He was a graduate of Jefferson Medical College, Philadelphia, in 1886, and formerly professor of ophthalmology at the Long Island College Hospital, Brooklyn.

Correspondence.

OSTEOPATHY.

TO THE EDITOR OF THE MEDICAL RECORD:

SIR:—In his note on Osteopathy to the MEDICAL RECORD of Oct. 27, it is quite evident that Dr. Beverly Robinson is not aware of the fact that at all of our large hospitals there is a corps of masseurs and masseuses doing better work than he ever dreamed of from such a source.

An excellent masseuse from a neighboring city called on me a short time ago and said, "The doctors in our town will not recommend massage, and their patients who need it go to the osteopaths." The inevitable result of this is that when the patients are benefited, as they sometimes are, their physicians are denounced for a conservative lot of old fogies, who do not want their patients cured in any other way than by the use of drugs; whereas they might just as well have had the honor and glory of the cure by advising massage at the proper time and seeing that it was correctly done. But many times patients do not ask advice of their physicians about such matters, and when they receive no benefit or are injured, then they come back to the fold of their own good shepherd much better sheep than when they departed. Especially is this the case with many of the patients of the orthopedic surgeons, who often have their spinal columns yanked in a most unmerciful manner by the osteopaths, when they ought to be kept quiet, and then they return meeker than Moses, and require a much more prolonged course of immobilization. Indeed, I am not so sure but that some of my orthopedic friends are highly tickled over this, though they say not a word. But what shall we say of the physician who is so lacking in backbone as quietly and placidly to look on while his patient is being treated by an osteopath? Surely he ought to know that in some cases valuable time is being lost; in others, that his patient is liable to be injured. We are told everything that the osteopath does is scientific, very scientific. Some even claim that it is nothing but scientific massage. Unfortunately for the patient, however, the result is too often *sigh-entific.*

Osteopathy is a word that has long been in use to signify disease of bone. It is the worst possible term that could have been cribbed for any form of manual treatment whatsoever. In the MEDICAL RECORD of August 16, 1879, I described all these people before they were conceived or begotten and while as yet there was none of them. Here are the words: "In almost every city of the United States, and, indeed, of the whole civilized world there may be found individuals claiming mysterious and magical powers of curing disease, setting bones or relieving pain by the immediate application of their hands. Some of these boldly assert that their art, or want of art, is a gift from Heaven, due to some unknown power which they call magnetism, while others designate it by some peculiar word ending with *pathy,* or cure; and it is often astonishing how much credit they get for their supposed genius by many of the most learned as well as by the most ignorant people."

Osteopathy is nothing but a crude, rough, awkward sort of massage or movement done by people who know little or nothing about either, and who assume to know everything and who shut their eyes to all that has ever gone before them in the way of manual treatment. It is doubly true what Dr. John K. Mitchell has said: "That if physicians had only been wideawake to the value of massage in suitable cases, the osteopath would never have had a chance." When osteopathy continues to thrive as it does now, it is time the general practitioner studied medicine. said a writer in the *St. Louis Courier of Medicine.*

PRESS CENSORSHIP—REPRESSION OF QUASI-MEDICAL MISINFORMATION—ARTIFICIAL PROTEIN—GLYCERIN FROM WASTE MATERIALS.

LONDON, October 12, 1917.

A PRESS censorship is a provocative subject, though with many it is treated as a simple necessity, its function being to prevent the dissemination of false and alarmist news and to suppress facts of which the knowledge might prove injurious. In matters of scientific and medical importance, such censorship might well be extended to the lay press when it proposes to deal with such matters; for the public forms its views, often lasting ones, from this press, which is its chief and frequently its sole source of information. Some astonishing statements are continually put forth, and give rise to as much amusement as instruction. A recent daily told its readers that "bottled blushes" could be purchased, and descanted thereanent on capsules of amyl nitrite! An equally noteworthy example is the extravagant claim for flavrine put forward by one whose ignorance of scientific matters is likely to do harm by promoting self-medication, with explosive compounds made at home. In view, therefore, of the dissemination of false or at least dangerously incomplete and inaccurate knowledge through the medium of the lay press, a censorship has been thought by some to be worth thinking about.

Science is being plumbed to its depths for agents to take the place of others which are fast disappearing. The demands of war on some classes of substances are stupendous, and spell exhaustion in different directions. Protein foodstuffs have been produced by the fermentation of solutions of sugar and ammonium sulphate, by the agency of yeast. Another noteworthy achievement is the production of glycerin from camp waste. Considerable quantities of this commodity have been obtained from waste fats and bones. It has been estimated that 14 pounds of household bones will yield enough glycerin to provide the charge for a shell of 18 pounds, and the quantity of glycerin recovered up to date is well over one thousand tons. When peaceful times return they should witness the cheapening of glycerin and several other medicinal substances, as the outcome of necessitous war-time research.

RED CROSS CANTEEN AT THE GARE DE L'EST—THE PROBLEM OF ABORTION—SURGICAL USES OF RUBBER—NEW Y. M. C. A. HOTEL FOR SOLDIERS.

PARIS, October 8, 1917.

THE night canteen No. 1, "Les Deux Drapeaux," operated by the American Red Cross in cooperation with Mlle. Richard, which has been opened at the Gare de l'Est, has proved itself an instantaneous success. The first night it was opened, men arriving close to midnight from Lengres and Belfort had passed ten hours in the train and arrived in Paris to find all restaurants closed.

The American Red Cross canteen, however, was open in the railway station, and they showed themselves most appreciative of the fact. The military authorities had advised Red Cross officials that perhaps there would be between thirty-five and fifty poilus who would avail themselves of the canteen, but, as a matter of fact, those in charge of the canteen served hot and comforting drinks to nearly 400 soldiers.

For a long time, just how long I would hesitate to say, the Academy of Medicine has been occupied with the study and discussion of the depopulation of France, not by the war, but by abortion. Many savants have taken part in this discussion and their suggestions and recommendations give evidence of the earnestness and profundity of their analysis, but the situation demands something more than discussion. One strong man with the will and determination to accomplish results would do more to resolve the situation than a dozen academicians.

The causes underlying the great increase in abortion are multiple and complex. Moral, social, economic, outside of such causes as alcoholism, syphilis, and tuberculosis. I do not pretend to have a solution to offer, but I do know that to achieve success measures must be taken that will fairly cause a social revolution; centuries of custom and usage that have slowly formed the basis of the evil that now threatens the life of the nation cannot be cured by palliative measures; the disease is deadly and the measures looking to a cure must be radical.

It has been suggested that the Government make a monetary provision for each child born out of wedlock, which is well, but what can they do to protect the mother socially? If the Government could pension every woman consenting to bear an illegitimate child to the extent that she would not be wholly dependent upon the good will of the community for the opportunity to earn her living; in other words, guarantee her against want, I venture to say the birth rate would be advanced to surprising proportions; but could the nation afford this burden?

Professor Delbet made a highly interesting communication to the academy respecting his experiences in the surgical use of rubber. He has employed elastic rubber to replace aponeuroses and muscular tissues and hard rubber to replace bone. He reported the case of a man in whom he resected 15 cm. of the upper part of the humerus, including the head, and replaced it with hard rubber, and the man is now using his arm.

All the comforts of home, all the conveniences of an American hotel—right here in Paris, for the American soldier and sailor. That is the description deserved by the Hotel du Pavillon, at 36 rue de l'Echiquier, as it is now being operated by the Y. M. C. A. Prices have been cut to a point to cover expenses. The price of a room with two beds and bath attached, which cost 20 fr. a day before the Y. M. C. A. took the hotel over, has been reduced to 10 fr.; a large single bedroom, for which the old price was 7 fr., now goes for 4 fr. to the soldier or sailor. For 3 fr. a day he can have a small single bedroom that formerly cost 5 fr.

There are 110 modern rooms, with hot and cold running water, telephones, and electric clocks, that are available at 4 fr. and up—and not so far up—in price. There are 110 rooms with everything but the running water that are to be had at 3 fr. and

up. Included in the furniture of every room is a Morris chair.

The man who does not rent a room with bath has a big bathroom within a few steps of his door.

Then, when he's all dressed up with no place to go, he has, on the first floor, lounge with pianos, phonograph, and easy-chairs; writing room with stationery and American and English magazines; billiard room with a real billiard table, and the dining room which has only to be seen to be appreciated.

Already sailors and soldiers from "somewhere in France" are making this first of Y. M. C. A. hotels their headquarters in Paris. Among the first arrivals were two young pigeons, which took up their residence outside the window of room 300. A waste basket now provides them with one of the conveniences of the hotel.

And, last but not least, there's an elevator—and it will carry you down as well as up, which is more than can be said for the average Paris "lift."

5. The Treatment of Wounds with Normal (Beef) Serum. Studies in Serum Therapy VI. Joseph H. Shortell, William F. Cotting, and Timothy Leary.
6. Physical Examination of Factory Employees: Two Thousand Consecutive Cases and the Defects Found. Raymond W. Cutler.

3. Anaphylactic Reactions to Normal Sera. Studies in Serum Therapy IV.—Timothy Leary, Frank H. Dunbar, and John W. Watson decided to carry out a series of skin tests on normal human beings, in order to determine human susceptibility to the local application of various animal proteids. This method seemed particularly applicable, first, because it was recognized that the toxic character of beef serum is exhibited in non-fatal doses in laboratory animals at the point of inoculation; and secondly, because in wounds the serum would be applied in most cases locally. Various substances used in the test were normal saline solution (control), human, beef, sheep, pig, goat, and rabbit sera were used, as well as horse and fowl sera, egg white (diluted 1—10), and milk. The sera and milk were fresh, undiluted, and unheated. Tests were made on 113 individuals. Some individuals gave skin reactions to most of the agents used, excepting the saline and human serum. The occurrence of a reaction to human serum in a small number of cases is interesting, but agrees with the finding of isolysins in human and other sera. Although precautions were taken to make the scratches as nearly alike as possible, an error from this source, due to variation in the traumatism, cannot be excluded. Notable is the grouping of the other sera, excepting that of the fowl. It will be observed that the reactions to beef, sheep, pig, and goat sera correspond, within the limits of error, to those obtained with horse serum, 16 slight, 15 moderate, and 2 marked. Chicken serum and egg white gave a high percentage of reactions, as would be expected from the recorded cases of egg poisoning. They refer to the work of Dr. Edwin Place, physician in chief, South Department, Boston City Hospital, who in a personal communication of unpublished work states that in preparation for the use of antitoxin in individuals who were known to be hypersusceptible to horse serum, he carried out a series of injections (1 to 10 cc. in arm or back) of antitoxic beef serum in over one hundred cases. Practically 90 per cent. of the cases exhibited a local reaction marked by the appearance within 24 hours of redness, swelling and tenderness about the site of the injection. This, though oftentimes extensive, subsided in all cases without local after-effects in two or three days. None of the children exhibited any other anaphylactic reaction, i.e. the reaction was purely local, in no case becoming generalized. This is in contrast to the reaction to horse serum, which, when it occurs, is usually delayed and general, marked by urticarias, etc.; rarely is there exhibited a purely local reaction. The antitoxic effect, as was to be expected, corresponded to the effect of using antidiphtherial horse serum. Their conclusions are drawn as follows: The results of these observations indicate that the skin reactions to unheated beef serum correspond closely to the reactions obtained with the sera of the other higher domestic herbivora, including the horse. The work of Dr. Place justifies a belief that beef serum, unheated, has only minor local toxicity, if any, in human beings, and can be used from this standpoint almost as safely as can horse serum. The observations of Dr. Place indicate that beef serum is safer than horse serum with reference to delayed anaphylactic responses, which follow so frequently the use of horse serum. The clinical application of beef serum in the treatment of wounds has been followed by no anaphylactic phenomena when the serum has been applied to wound surfaces. In six cases injections of serum were made, either subcutaneously or into the deep tissue. The amount injected was about 15 cc. In three of these cases chills occurred within two hours of the injection. In only one case was the chill marked, the temperature reaching 103°. In no case did a delayed anaphylactic reaction appear.

5. The Treatment of Wounds with Normal (Beef) Serum. Studies in Serum Therapy VI.—Joseph H. Shortell, William F. Cotting, and Timothy Leary employed a definite technique in the application of normal (beef) serum to the treatment of wounds of various types. Cellulitis, infected wounds, acute osteomyelitis, septic, ulcers, burns, and skin grafts were handled by this method and they state that the results justify the following conclusions: (1) Serum will control a septic process, wherever contact is made between the serum dressing and the infected tissue. (2) It is absolutely harmless to normal tissue. (3) As a prophylactic agent in fresh wounds it is of value. (4) Serum is a most marked stimulant of granulations. Grafting can and should be practiced earlier following the use of serum than under any other agent. (5) Injections of unheated beef serum are followed by rises in temperature, usually slight, perhaps with chill, but the reactions are short and not severe. Used as a dressing to wounds, no matter how large the surfaces are, it gives rise to no anaphylactic response.

1. Antitoxin for Gaseous Gangrene.—Carroll G. Bull gives the results of experimental work from the laboratories of the Rockefeller Institute for Medical Research on the production of antitoxin for gaseous gangrene. He states that it is a well-known fact that individual strains of the *Bacillus welchii* group may possess widely different morphological and cultural properties, and, according to previous work, a great majority of the strains are immunologically individualistic. From the point of view of developing a specific immune therapy, twenty-nine strans of the gas bacillus have been col-

lected from widely different sources and tested for toxin production, considering especially the character and severity of the lesions on animal inoculations, as well as the effect of a monovalent antitoxic serum on their pathological action. Twelve of the strains were isolated from cases of gaseous gangrene occurring among the wounded on the Western battle front; two were obtained from cases of gaseous gangrene in New York City, while the others were isolated from local saprophytic sources—milk, garden soil, feces, etc. The results were that each strain so far studied secretes a toxin which is neutralized by an antitoxic serum obtained by immunizing animals with the toxin from any individual strain. The toxins were qualitatively indistinguishable, varying, however, in potency. From the results obtained it is fair to conclude, therefore, that the same toxin is common to all members of the *Bacillus welchii* group. The results obtained with the preventive and therapeutic applications are very encouraging. They derive significance, in the first place, from the fact that gas bacillus infections in guinea pigs and other susceptible animals are comparable with infections with this organism in man. The experimental infections in the guinea pig differ, however, from the natural infections in man, since man possesses a higher natural resistance to infection with this organism, and such massive infections do not occur in nature. The protected guinea pigs manifested perfect immunity to hundreds of lethal doses of the bacilli several days after the antitoxin had been administered. It seems reasonable, therefore, to predict that the infection in man will not develop as long as his body fluids and tissues contain an adequate quantity of the antitoxin. The possibilities of passive prophylaxis, the author maintains, have certain natural limits of time, depending upon the rapidity of elimination of the foreign serum. The experimental data presented and practical experience with antidiphtheritic and antitetanic antitoxins indicate that, in all probability, a passive immunity to Bacillus welchii infection of at least two weeks' duration can be conferred upon man. An immunity of ten days' duration from the time of exposure to infection will be sufficient in the great majority of instances, since only sporadic cases of Bacillus welchii infection arise after this time, the greatest number occurring forty-eight hours after exposure. In the light of the results obtained in treating the infection in guinea pigs, it is reasonable to hope that the antitoxin will be of value also as a therapeutic agent. The indications are that early infections can be readily arrested and the more advanced and severe ones ameliorated, if not wholly checked, so that surgical interference may be resorted to with greater possibilities of effectiveness. It can be stated here, parenthetically, (1) that the antitoxin is being prepared on a large scale in horses, and that very potent serums have been obtained; (2) that a few cases of gaseous gangrene in man have already been treated, in which the efficacy of the antitoxin was unmistakable. The antitoxin was administered intravenously and locally about the wound. Bull summarizes the results of his work as follows: (1) Twenty-nine strains of the Bacillus welchii group have been found to produce toxins which are qualitatively indistinguishable. (2) It has been possible to confer on guinea pigs a passive immunity of about two weeks' duration to Bacillus welchii toxin through a protective administration of the antitoxin. (3) Guinea pigs which had received a prophylactic dose of Bacillus welchii antitoxin exhibited pronounced resistance to infection with the virulent bacilli for a period of twelve days. (4) The opinion has been expressed that it will be possible to prevent gas bacillus infections in man through a protective use of the antitoxin, and that developed cases of the infection may be controlled by therapeutic application of the same agent. (5) A few cases of gaseous gangrene in man have been treated in which the efficacy of the antitoxin was unmistakable.

2. **"Truth About Intraspinal Injections in Treatment of Syphilis of Nervous System." A Reply.**—John A. Fordyce takes exception to some of the statements made in an address by the chairman of the Section on Nervous and Mental Diseases, Dr. Bernard Sachs, read at the Sixty-eighth Annual Session of the American Medical Association entitled "Truth About Intraspinal Injections in Treatment of Syphilis of the Nervous System." He states that if the statements contained in that article are accepted by the medical profession as a final and correct judgment of this new therapeutic procedure, an enormous amount of harm will result in that numerous victims of syphilis of the nervous system will be deprived of their only chance to regain health and economic efficiency. The attempt to discredit the value of serologic examination of the spinal fluid as a diagnostic procedure and guide to treatment should not be permitted to gain credence without a word of protest. In the address in question there are several statements that are entirely at variance with the experience of his colleagues and himself, who have employed the method over a period of years in the manner they consider technically correct. They have seen numerous patients, treated for months intensively by salvarsan given intravenously with little or no clinical improvement, entirely relieved of tabetic pains, crises, bladder symptoms and sexual impotence, and with a marked improvement in their ataxic gait after the institution of intraspinal treatment. Six case histories are given showing the results obtained by the correct employment of the intraspinal injections of salvarsan. Fordyce sums up his objections to the statements in the first article, as follows: (1) In tabes, certain types of cerebrospinal syphilis like mentingitis, meningo-myelitis, meningo-encephalitis and in optic atrophy with positive findings in the fluid, intraspinal treatment succeeds in relieving or curing the conditions after failure of intravenous and other treatment. (2) It is the only procedure that can be employed after the intravenous treatment fails or when the patient develops an intolerance to arsenic. (3) With proper technique and experience, it is less dangerous than intensive intravenous treatment. (4) In paresis with stigmata of degeneration, the most to be hoped for is temporary arrest of the encephalitis. There are borderline cases of meningo-encephalitis which simulate paresis and which are curable by the treatment in question. (5) The criticism of the method is based largely on the results following imperfect technic and by its employment in cases without clear indications afforded by spinal fluid examination. Aside from these reasons, it has been condemned after short and imperfect trials. In some cases the existing lesions are activated by early injections and cured by persistence in the treatment. (6) The author's statement that it is regrettable that changes in biologic findings should be made the criterion of the efficiency of any therapeutic method is unfortunate from the standpoint of the patient as well as the investigator. With the exceptions noted in the body of the article in paresis and preparetic conditions, when a temporary remission may occur and not be indicated in the fluid, there is an intimate relationship between the clinical symptoms and the fluid findings. It is not difficult to select individual cases in which the Wassermann and globulin reactions are unchanged after prolonged treatment; but conclusions based on such exceptional cases are one-sided, unfair, and fail entirely to interpret or correlate the fundamental principles involved. If reliance is placed on

clinical improvement alone as a criterion of the action of our remedies and the fluid changes disregarded, few, if any, permanent cures will be achieved, and sooner or later the patient's condition will relapse. There is as much reason for basing the efficiency of a therapeutic procedure on the changes in the biology of the fluid as there is in using the blood Wassermann as a test of the value of treatment of syphilis in general. If we were to discard the positive knowledge acquired in the past few years as a result of systematic examination of spinal fluids in syphilis, we should have vague ideas as to the time the fluid is infected, no clear conception of the difference between active and abortive tabes, and no method of differentiating early paresis from conditions that simulate it. Neurasthenic states, headaches, phobias, vague changes in mentality, crises, or impairment in the sexual function are constantly overlooked or wrongly diagnosed by the pure clinician. Arteriosclerosis, chronic alcoholism, and diabetes may cause symptoms easily mistaken for the syphilitic syndrome. (7) The future of the syphilitic individual and the hope of anticipating or arresting the incurable degeneration is largely dependent on early and systematic examination of the spinal fluid.

6. Pneumococcal Meningitis. — C. Worster-Drought and Alexander Mills Kennedy based their observations upon a study of nine cases of pneumococcal meningitis which came under their direct care, the ages of the patients varying between the wide limits of three months and forty-nine years. In five cases the disease was the so called primary form—that is, no lesion conceivably due to active pneumococcal infection was discovered elsewhere. This diagnosis, in three cases, was confirmed by postmortem examination; in the remaining two an autopsy was not obtainable, but, clinically, no other lesion could be detected. In four cases meningitis occurred as a secondary infection. From the day of onset the course of the disease varied from three to fifteen days' duration in different cases. With two adults, aged twenty-two and forty-one, both cases of the primary form confirmed by postmortem examination, the course of meningitis was extremely acute, lasting only three days; the temperatures were never below 101°, and often reached 104°. Five other cases were also acute; the one in which, postmortem, the sphenoidal sinus was found filled with pus died four days after the commencement of headache. Both the children in whom meningitis occurred secondarily to lobar pneumonia lived only two days after the appearance of meningeal symptoms. In none of the above cases did any lasting improvement follow the evacuation of cerebrospinal fluid from the intrathecal space. A man, aged twenty-three, in whom meningitis occurred secondarily to otitis media, ran a course of nine days' duration, being continually delirious in spite of the daily withdrawal of 55 to 100 c.c. of cerebrospinal fluid, before sinking into coma. An infant of three months also continued for eight days acutely ill and with occasional convulsions. The courses of two other cases, both primary forms, were somewhat subacute; one was an infant, aged four months, who lived for twelve days with retracted head, arched spine, and occasional vomiting. Towards the end convulsions were frequent. The second subacute case is deserving of special mention. Meningitis having been diagnosed by the rigidity of the neck muscles, Kernig's sign, etc., its causative organism can only be determined by bacteriological examination of the cerebrospinal fluid. Even in the presence of pneumonia meningitis is not necessarily pneumococcal, as, in occasional cases of cerebrospinal fever, a bronchopneumonia may at first mask the meningeal symptoms. The majority of the cases described above were sent into hospital with a diagnosis of cerebrospinal fever; it was only upon finding pneumococci in the cerebrospinal fluid that their true nature was revealed. It is frequently possible to diagnose tuberculous meningitis clinically but, at the present time, it is safer to regard any other examples of meningitis as meningococcal until proved otherwise. The treatment of pneumococcal meningitis is at present most unsatisfactory. The nine cases recorded here serve to demonstrate the failure of repeated lumbar puncture. Each patient was punctured at least once daily, and in some cases every twelve hours, the subarachnoid space being drained on each occasion, until practically no more fluid would flow. As a result of the drainage the symptoms were occasionally alleviated for a time, but the ultimate result was not affected. Vaccines may be of value, but it is seldom that a case lasts sufficiently long for vaccine therapy to have an effect. They found hexamine of no value in the treatment of meningitis. Since the chief therapeutic properties of the drug appear to be due to its oxidation into formaldehyde, which takes place only in an acid medium, it probably has little or no action in meningitis. In the course of the chemical examination of numerous samples of cerebrospinal fluid from cases of meningitis, they found less than 2 per cent. giving a very faintly acid reaction. The fluid is usually faintly alkaline, but occasionally neutral; the indicators used were litmus, phenolphthalein and methyl orange. Hexamine can be detected in the cerebrospinal fluid within an hour of administration by the mouth, but the Burnam-Ramini test fails to demonstrate the presence of free formaldehyde. Lamar, working with monkeys, showed that sodium oleate attacked and dissolved pneumococci, and, when combined with a specific anti-pneumococcic serum had a decided therapeutic effect on pneumococcal meningitis, even when the organisms were multiplying in the blood stream. The action, however, is restricted to the particular type of pneumococcus from which has been produced the immune serum in the mixture of serum and sodium oleate. When the infecting pneumococcus was different in type from that represented by the immune serum no therapeutic action resulted. When, therefore, a satisfactory polyvalent immune serum is forthcoming the most promising method of treatment would seem to consist in the intrathecal injection of the antipneumococcic serum mixed with a solution of sodium oleate.

Le Progrés Mèdical.

September 15, 1917.

Medical Relations Between Latin-America and France.—M. G. states that the penetration of German science into the Latin countries has never been more than superficial, quoting from an address by Roger delivered last year. The Western countries of Continental Europe and the South American states comprise an ethnic group having a common origin, aspirations, ideas, and culture. This intellectual unity is maintained by a constant exchange of scientific books and publications. French works always have a good market in Latin-America, while German works circulate only in translation, French, and to some extent Italian. Since French is readily understood throughout South America, and French works are truly representative of Latin culture, German literature is much more an exotic even in translation. Naturally in the exchange of books and periodicals the French give much more than they receive. Paris exchanges theses with the Universities of Buenos Aires and Rio. All official publications from the universities of Brazil, Argentine, Uruguay and Cuba are also received in France along with certain publications from Mexico, Paraguay, Bolivia, Caracas and Montevideo. This service should be improved. At present there are from 60 to 70 South American students in the University of Paris, and there are at this moment 16 former internes of Paris hospitals engaged in practice in South and Central America. But aside from the student contingent many graduates in medicine come to Europe to complete their studies. As a matter of fact, Latin-America has facilities for teaching her undergraduates, but is less well equipped for post-graduate

work. The graduates have never been organized, and statistics concerning them are lacking. It is to be hoped that after the war is over this omission will be rectified. The French Institute for Colonial Medicine registered 224 pupils during 1902-1913. About a third of these were South Americans by birth. There is also in France a Society of Colonial Medicine, and another of Exotic Pathology, both of which have among their correspondents a number of eminent South American savants. It is highly desirable that the custom of exchange of university professors between the two hemispheres be inaugurated. This holds good for all sciences. Closer contact between the two hemispheres would perhaps have caused it to be known that an obscure health officer at Guadaloupe was the real pioneer in the demonstration of the mosquito transmission of yellow fever. Carlos Finlay took up the matter and saw it through. Further, several Frenchmen sent on a mission to Brazil proved after four years' work that the offending mosquito was the stegomyia. The indirect outcome of this work of Marchoux, Salimbini and Simond was the great prophylactic movement which culminated in the foundation of the Oswaldo Cruz Institute in Rio, the transactions of which appear simultaneously in Portuguese and French. The French and South Americans have collaborated in the warfare against poisonous serpents. It is to be regretted that certain epoch-making labors like those of Chagas on trypanosomiasis and of Crawell and Herrera Vegas on echimococcus disease have not yet appeared in French.

Norsk Magazin for Laegevidenskaben.

September, 1917.

Periarteritis Nodosa (Non-Syphilitic).—Harbitz reports a case of this affection naturally with autopsy. This disease was first described in 1866 in a patient with a complication of diseases of supposed syphilitic nature or origin although there were no characteristic lesions of that affection. In the fifty years which have elapsed some 35 cases have come to autopsy chiefly in German, Austrian, and Italian clinics. It is noteworthy that not a case has yet been reported in the English language. The author is able to add one to the few known Scandinavian cases. Patient was a male of 22. The initial symptoms were pains in the feet which were associated with muscular weakness. In the military hospital he received salicylic acid and KI. A general examination showed a normal thorax and abdomen. The feet were not swollen but presented tender points, which were also elicited along the back of the legs and thighs and over the head of the fibula. Patient who had never been ill in his life, was referred to the neurological department where the cranial nerves and those of the upper extremities were pronounced normal. The lower extremities showed no motor anomalies save for slight muscular weakness. All movements could be performed normally. Aside from sensitiveness of the muscle bellies there were tender pressure points. The bones were not tender in the shafts but the fibula heads and external malleoli were sensitive to pressure. The gait was paretic. There was a daily subfebrile temperature rise. Under treatment there was some improvement but several weeks later headache appeared with paresthesiæ in the upper extremities. The Wassermann was negative with positive Pirquet. Next there was a more rapid pulse, palpitation, and a blood pressure of 160. The urine, at first normal, had now become nephritic. The patient had now been ill for six months. At this juncture new symptoms developed—epigastric tenderness, vomiting, jaundice, dyspnea, edema, diarrhea, hemoptysis, ascites. The heart had been slowly enlarging, impulse now two or three finger breadths outside of mamillary line. Pulse became irregular and unequal. Death occurred after vomiting of blood and passage of same per rectum. Autopsy: the encephalon presented nothing abnormal, the arteries at the basis cranii being found intact. The heart was markedly hypertrophic in both ventricles with general dilatation of all cavities. The valves were normal, myocardium showed evidence of a peculiar form of degeneration, coronary arteries normal but the smaller branches were the seat of certain circumscribed thickenings of the intima. There was fluid in both pleuræ. The autopsy diagnosis was periarteritis nodosa affecting chiefly the arteries of the omentum (greater and less). The same process was beginning in the coronaries and arteries of the stomach and kidneys. There was degeneration and necrosis of the myocardium, hemorrhagic nephritis, necrotic areas with hemorrhage in the stomach and intestine. The unknown infection by attacking some of the smaller arteries had led to ischemic and degenerative changes in important viscera.

Annali d'Igiene.

August 31, 1917.

Alimentation of Italian Soldiers.—The present number of the Annali contains three articles on this subject. Rho, after quoting from authorities as to the number of grams of protein requirement per kilo of body weight, refers to another method of computation, viz., the number of protein calories for a man weighing 154 pounds. This has been fixed as low as 257 calories, but little over 60 gm. by weight. The Italian daily war ration has been 375 gm. of meat, equivalent to 151 gm. protein. This is nearly double the peace allowance. It is, of course, not to be understood straightway that the soldier actually consumes that amount, but in any case such an allowance of protein is not in harmony with modern teaching, for we know that for hard, sustained labor fuel food is required in amounts proportioned to the work of the machine. Luciani, the great Italian physiologist, has accepted the low protein requirement fixed by Chittenden, Hindhede, and others. The possible ill effects of the excessive consumption of meat may be left out of consideration in comparison with the fact that 30,000 head of slaughter animals are perhaps being wasted every month. The Italian peasant, moreover, has been raised without much animal protein, and it seems bad judgment to place him on a diet relatively rich in that food element. The number of daily calories necessary for the Italian soldier should not exceed 3000, which number should perhaps comprise 257 of protein for a man of 154 pounds. Baglioni states that the protein requirement is the only debatable subject. At the beginning of the war the soldier was allotted 200 gm. lean beef daily. This was made into beef stew, in which the soldier dipped his bread. The beef fat extracted by boiling remained in the stew and averaged 80 gm. Rice or macaroni was added and the ration called for canned tomatoes. The daily bread amounted to 750 gm. This ration proved very monotonous, and on one day in the week 100 gm. of cheese were given. Later, on alternate days, the beef was partly replaced by pork, mutton, or fish, while the rice and macaroni were also in part replaced by legumes and potatoes. As the active war ration called for extra meat the original 375 gm. were cut down to 250 and the difference made up with legumes, macaroni, or cheese, according to the particular day of the week.

Belli gives the minimum daily allowance of the sailors as follows: Total calories, 2700-2800; protein, about 90 gm. (of which 26 to 38 in the form of animal protein). The total protein consumed weekly is 600 gm.; of fats, 25 to 28 gm. The total daily consumption of carbohydrates is 500 to 600 gm. The actual quantity of daily bread is 550 gm. These figures were reached by experiments on a diet squad of marines.

Lymphatism and Suicide.—The recent claim that young suicides are apt to be of lymphatic constitution has been investigated by Hammar, who examined eighteen suicides aged from 17 to 35, with seventeen victims of accidents of the same span for controls. The thymus was found to be actually smaller on an average in the suicide series.—*Vierteljahresschrift für gerichtliche Medizin.*

Failure of the Wassermann in Certain Syphilitics.—Oestreicher cites a certain type of syphilitic who appears to be in vigorous health with healthy wife and children, has no suspicion of infection, has never been treated. The lesions, of the tuberculo serpiginous type, yield readily to potassium iodide. These subjects may give a negative Wassermann.—*Deutsche medizinische Wochenschrift.*

NEW YORK ACADEMY OF MEDICINE.

SECTION ON PEDIATRICS.

Stated Meeting, Held October 11, 1917.

DR. ROGER H. DENNETT IN THE CHAIR.

Amaurotic Family Idiocy. — Dr. SARA WELT-KAKELS presented this patient, a female infant that came under her observation in March, 1916, at which time she was five months of age. The child showed the usual picture of amaurotic family idiocy, and also contractures of the limbs, especially of the upper extremities. As there was nothing in the family or personal history that gave a clue to the etiology of the disease, and in view of the theory that this condition might be due to some form of toxemia, some of the spinal fluid was withdrawn from the spinal canal of the child and injected into animals. After some weeks the brain and spinal cords of these animals were examined, but no changes had taken place.

Dr. HENRY KOPLIK said that he had seen over one hundred cases of amaurotic family idiocy, but he had never seen a case with this form of contracture, which might be taken for Little's contracture. Spasticity was not uncommon, but it was uncommon to find this form of contracture in the upper extremities. As the majority of these cases of amaurotic family idiocy were breast fed, it was difficult to account for them except on the theory that they were due to toxemia and it was for this reason that the spinal fluid from this case was injected into animals. Although the results of these experiments were negative, they, nevertheless, marked an advance in their knowledge of this condition. Dr. Koplik said that he was inclined to believe with Hirsch that the condition was congenital and that possibly it was a toxemia; it was a question whether it might not be a form of toxemia of pregnancy.

Chronic Internal Hydrocephalus; the Newer Methods for Its Recognition and Treatment.—Dr. CHARLES A. ELSBERG presented this paper, which was based upon a study of forty cases of hydrocephalus in infants and young children at the Neurological Institute and Mount Sinai Hospital. After reviewing recent investigations with reference to the secretion and circulation of the cerebrospinal fluid, he stated that these investigations had taught us that there were three different types of hydrocephalus—namely, that due to obstruction in the aqueduct of Sylvius or in the foramina of Magendie and Luschka, that due to diminished absorption, and that due to hypersecretion, or a combination of these. For a differentiation of these types from one another, Dandy and Blackfan, and Frazier and Peet had devised a method in which phenolsulphonephthalein was used as an indicator. After introduction into the ventricles phenolsulphonephthalein appeared in the urine in from two to twelve minutes; from 12 to 20 per cent. was excreted within two hours. When introduced into the subarachnoid space the dye appeared in the urine in from six to eight minutes, and from 35 to 60 per cent. was excreted in two hours. The dye passed rapidly from the ventricles into the subarachnoid space and appeared in the spinal fluid in from one to three minutes. As an indication of the amount of absorption from the arachnoid space neutralized phenolsulphonephthalein solution was employed. After examination had shown that the kidneys functionated normally, a lumbar puncture was done, a cubic centimeter of fluid withdrawn, and a cubic centimeter of the neutral phenolsulphonephthalein (6 milligrams) was injected. It was important that the solution be neutralized, as the alkaline solution was irritating to the central nervous system. All the urine secreted during the succeeding two hours was collected and examined. If less than 30 per cent. of the phenolsulphonephthalein had been excreted, there was diminished absorption from the subarachnoid space. In the majority of cases in which the absorption was below normal they had obtained values between 2 and 14 per cent. If after introduction of the dye into the ventricles, the puncture being made through the lateral angle of the fontanelle, the dye failed to appear in the lumbar puncture fluid within ten minutes, the case was one of obstructive hydrocephalus, and if the patient was under anesthesia, the proper operative interference, puncture of the corpus callosum, could be done at once through the trephine opening, which was made for the purpose of giving the injection. The trephine opening should always be made near the median line, just behind the coronal suture. In infants the injection could be made through the lateral angle of the anterior fontanelle. If these examinations showed that the normal communication between the ventricles and the subarachnoid space existed, and that there was either a normal or a subnormal absorption of fluid from the arachnoid space, the next step was to determine whether the secretion of the spinal fluid was greater than normal. A lumbar puncture was done every day or every other day. Where the secretion of the fluid was normal, the quantity of fluid obtained at each puncture and the pressure of the fluid became steadily less after the first two or three punctures. In hypersecretion, however, the amount of fluid obtained and the pressure under which it escaped remained constant for long periods. The occurrence of unilateral obstructive hydrocephalus might be determined by separate injections of phenolsulphonephthalein into each lateral ventricle. Of the forty cases of chronic hydrocephalus in this series, ten were obstructive, thirty nonobstructive, eighteen nonobstructive with diminished absorption, six nonobstructive with hypersecretion, and six nonobstructive with diminished absorption and hypersecretion. In hydrocephalus due to obstruction in the aqueduct of Sylvius or the foramina of Magendie and Luschka a new channel between the ventricles and the subarachnoid space should be made by puncture of the corpus callosum. By a simple, technically easy operation, a small opening was made near the median line, the dura incised, and the cannula passed by the side of the falx cerebri, through the corpus callosum, into a lateral ventricle. The opening was then enlarged by manipulation of the cannula, which was then withdrawn and the dura and scalp closed by suture. In properly selected cases, in which actual obstruction had been demonstrated, the results of this little operation were very satisfactory, and a complete cure might be effected. This was the most favorable variety of hydrocephalus for treatment up to the present time. There was some evidence to show that puncture of the callosum might be worthwhile trying in patients with obstructive hydrocephalus in whom subarachnoid absorption had been demonstrated to be below normal. In cases of hydrocephalus due to hypersecretion, a lumbar puncture should be done every day and the patient should be given thyroid extract in doses up to the physiological limit. From 15 to 30 c.c. of cerebrospinal fluid should be withdrawn at each puncture. The improvement would begin only after several months of treatment, and when the lumbar puncture demonstrated a diminished secretory activity of the choroid plexus. In hydrocephalus due to hypersecretion a certain number of satisfactory results could be obtained by a combination of thyroid feeding and repeated lumbar puncture. Hydrocephalus due to diminished absorption was the type most unfavorable for treatment. Repeated lumbar puncture and thyroid feeding might be tried, but in their experience had resulted in very little improvement. They had not tried to drain the fluid into any of the cavities of the body, as they felt convinced that real success could not be expected from any of the methods thus far devised. In those who had had chronic hydrocephalus the size of the head would always remain larger than normal, but if there was papilledema, this would rapidly subside under successful treatment and there would be improvement in the eyegrounds and vision. If ataxia had been of long standing it would require years for its complete disappearance, though marked improvement would occur within a few weeks after operation.

Dr. HENRY KOPLIK said he had been watching the progress of Dr. Elsberg's work and had learned a great deal from it during the last few years. He did not think any great advance could be made in the treatment of hydrocephalus until we knew more of its etiology. If the choroid plexus played the part it was supposed to play in the production of hydrocephalus it
